ABSTRACT

Techniques are discussed for Monte-Carlo evaluation of several filters in a digital fire control system performing against an aircraft trajectory developed to simulate a diving attack. The programs developed are designed to allow for future modeling work in a three-dimensional theater of operations with expedient selection of the options that are discussed, and a comprehensive user's guide is provided. Comparison is made between a model of the filter currently used in the MK-86 Digital Fire Control System and some promising combinations of the several options available.

I. INTRODUCTION

With the increasing cost and complexity of modern gunfire control systems there exists a correspondingly increasing need for thorough evaluation of simulated performance with accurate models before major commitment is made.

Specifically, the MK-86 Digital Gunfire Control System has come under such scrutiny and this thesis is one in a series designed to define, evaluate and offer alternative approaches to the existing system. While the original motivation for the study in this thesis was to explore alternative techniques to those used in the existing system, the resulting derivations and computer programs lend themselves to other system modeling situations within certain restrictions. The development of this thesis is intended to allow future modeling work to easily take advantage of the results contained herein.

The pattern followed in a typical cycle of the gunfire control system is the acquisition of data by a radar, analysis of the measurements in a filtering section, and the generation of gun orders in a third general section. The entire model should study all of these segments, but in order to simplify the problem each segment may be studied separately. This thesis is designed for studying the filtering section and assumes that input data is available from a

typical radar and that the results would be used by another section to generate the gun orders.

In order to evaluate possible filtering methods for analyzing the radar data it was necessary to generate realistic, simulated radar measurements for the model. Therefore, a hypothetical track was developed with the capacity for variation to provide the necessary input data. In addition, the various special features that are presented in this thesis were organized in the computer simulation for straightforward selection and implementation thus offering maximum flexibility for evaluation of the various filtering methods. This designed-in choice of options was intended, also, to lend the general program to other applicable situations.

II. PROBLEM DESCRIPTION

A. KALMAN FILTER THEORY

Sequential estimation is characterized by the serial recursive processing of observations taken in time sequence. The result of every processing cycle is the current best estimate of the vector being estimated. This estimate therefore embodies all observation data up to and including the current observation. As a new observation is made, the current estimate is updated to reflect this most recent data. In such an estimation scheme the calculations are identical in nature from cycle to cycle so they are ideally suited for implementation on a digital computer.

The Kalman filter [1] is a recursive filter of the type applicable to a digital fire control system in which discrete observations are available from the radar. The filter offers the capability of not only generating estimates of the observed system's states but, also, of predicting future system (or plant) states.

The linear discrete system for which the Kalman filter is designed is characterized by the state and output equations

$$\underline{x}(k+1) = \underline{\phi}\, x(k) + \underline{\Delta}\, \underline{u}(k) + \underline{\Gamma}\, \underline{w}(k) \qquad (1)$$

$$\underline{z}(k) = \underline{H}\, \underline{x}(k) + \underline{v}(k) \qquad (2)$$

where

$\underline{x}(k)$ is the n-dimensional state vector at time $t = kT$,

$\underline{u}(k)$ is the p-dimensional deterministic input vector at time $t = kT$,

$\underline{z}(k)$ is the m-dimensional vector of measurements or observations taken at time $t = kT$,

$\underline{w}(k)$ and $\underline{v}(k)$ are q-dimensional and m-dimensional noise processes, respectively, at time $t = kT$,

$\underline{\phi}$ is the n x n state transition matrix--assumed to be known,

$\underline{H}$ is the m x n observation matrix--assumed to be known,

$\underline{\Delta}$ and $\underline{\Gamma}$ are n x p and n x q matrices, respectively, which relate the deterministic and non-deterministic forcing terms to the state vector --they are assumed to be known,

T is the time between measurements, and k is a non-negative integer.

The noise statistics are summarized below

$$E[\underline{v}(k)\ \underline{v}^T(j)] = \underline{R}(k)\ \underline{\delta}(k,j) \tag{3}$$

$$\underline{\Gamma}\ E[\underline{w}(k)\ \underline{w}^T(j)]\underline{\Gamma}^T = \underline{Q}(k)\ \underline{\delta}(k,j) \tag{4}$$

$$E[\underline{v}(k)\ \underline{w}^T(j)] = 0 \text{ for all } (k,j) \tag{5}$$

$$\underline{\delta}(k,j) = \begin{cases} 0 & k \neq j \\ 1 & k = j \end{cases} \tag{6}$$

It is assumed that the initial state is a random variable with known mean and covariance

$$E[\underline{x}(0)] = \underline{\hat{x}}_o,\ E\left\{[\underline{x}(0) - \underline{\hat{x}}_o][\underline{x}(0) - \underline{\hat{x}}_o]^T\right\} = \underline{P}_o \tag{7}$$

In addition, it is assumed that the measurement noise and initial state are uncorrelated

$$E[\underline{x}(0)\ \underline{v}^T(k)] = 0 \text{ for all } k \tag{8}$$

and that the forcing noise and initial state are uncorrelated

$$E[\underline{x}(0)\ \underline{w}^T(k)] = 0 \text{ for all } k \tag{9}$$

The Kalman filter equations are summarized below

$$\underline{G}(k) = \underline{P}(k/k-1)\ \underline{H}^T[\underline{H}\ \underline{P}(k/k-1)\ \underline{H}^T + \underline{R}(k)]^{-1} \tag{10}$$

$$\underline{P}(k/k) = (\underline{I} - \underline{G}(k)\ \underline{H})\ \underline{P}(k/k-1) \tag{11}$$

$$\underline{P}(k+1/k) = \underline{\phi}\ P(k/k)\ \underline{\phi}^T + \underline{Q}(k) \tag{12}$$

$$\hat{\underline{x}}(k/k) = \hat{\underline{x}}(k/k-1) + \underline{G}(k)[\underline{z}(k) - \underline{H}\ \hat{\underline{x}}(k/k-1)] \tag{13}$$

$$\hat{\underline{x}}(k+1/k) = \underline{\phi}\ \hat{\underline{x}}(k/k) + \underline{\Delta}\ \underline{u}(k) \tag{14}$$

where the notation (k/k-1) is defined as a condition at time $t = kT$ given information up to and including time $t = (k-1)T$. The matrices in these equations are

- $\underline{G}(k)$ - n x m gain matrix
- $\underline{R}(k)$ - m x m covariance matrix of measurement error
- $\underline{P}(k/k)$ - n x n covariance matrix of estimation error
- $\underline{I}$ - n x n identity matrix
- $\underline{P}(k+1/k)$ - n x n prediction covariance matrix
- $\underline{Q}(k)$ - n x n covariance matrix of state excitation defined as $\underline{\Gamma}\ E[\underline{w}(k)\ \underline{w}^T(k)]\ \underline{\Gamma}^T$
- $\hat{\underline{x}}(k/k)$ - n x 1 optimal (minimum variance) estimates of $x(k)$
- $\underline{z}(k)$ - m x 1 observation vector
- $\hat{\underline{x}}(k+1/k)$ - n x 1 optimal predicted value of $\underline{x}(k)$.

A block diagram of the discrete plant and Kalman filter is shown in Figure 1.

The Kalman filter takes advantage of all previous state measurements, $\underline{z}$, along with their respective error estimates,

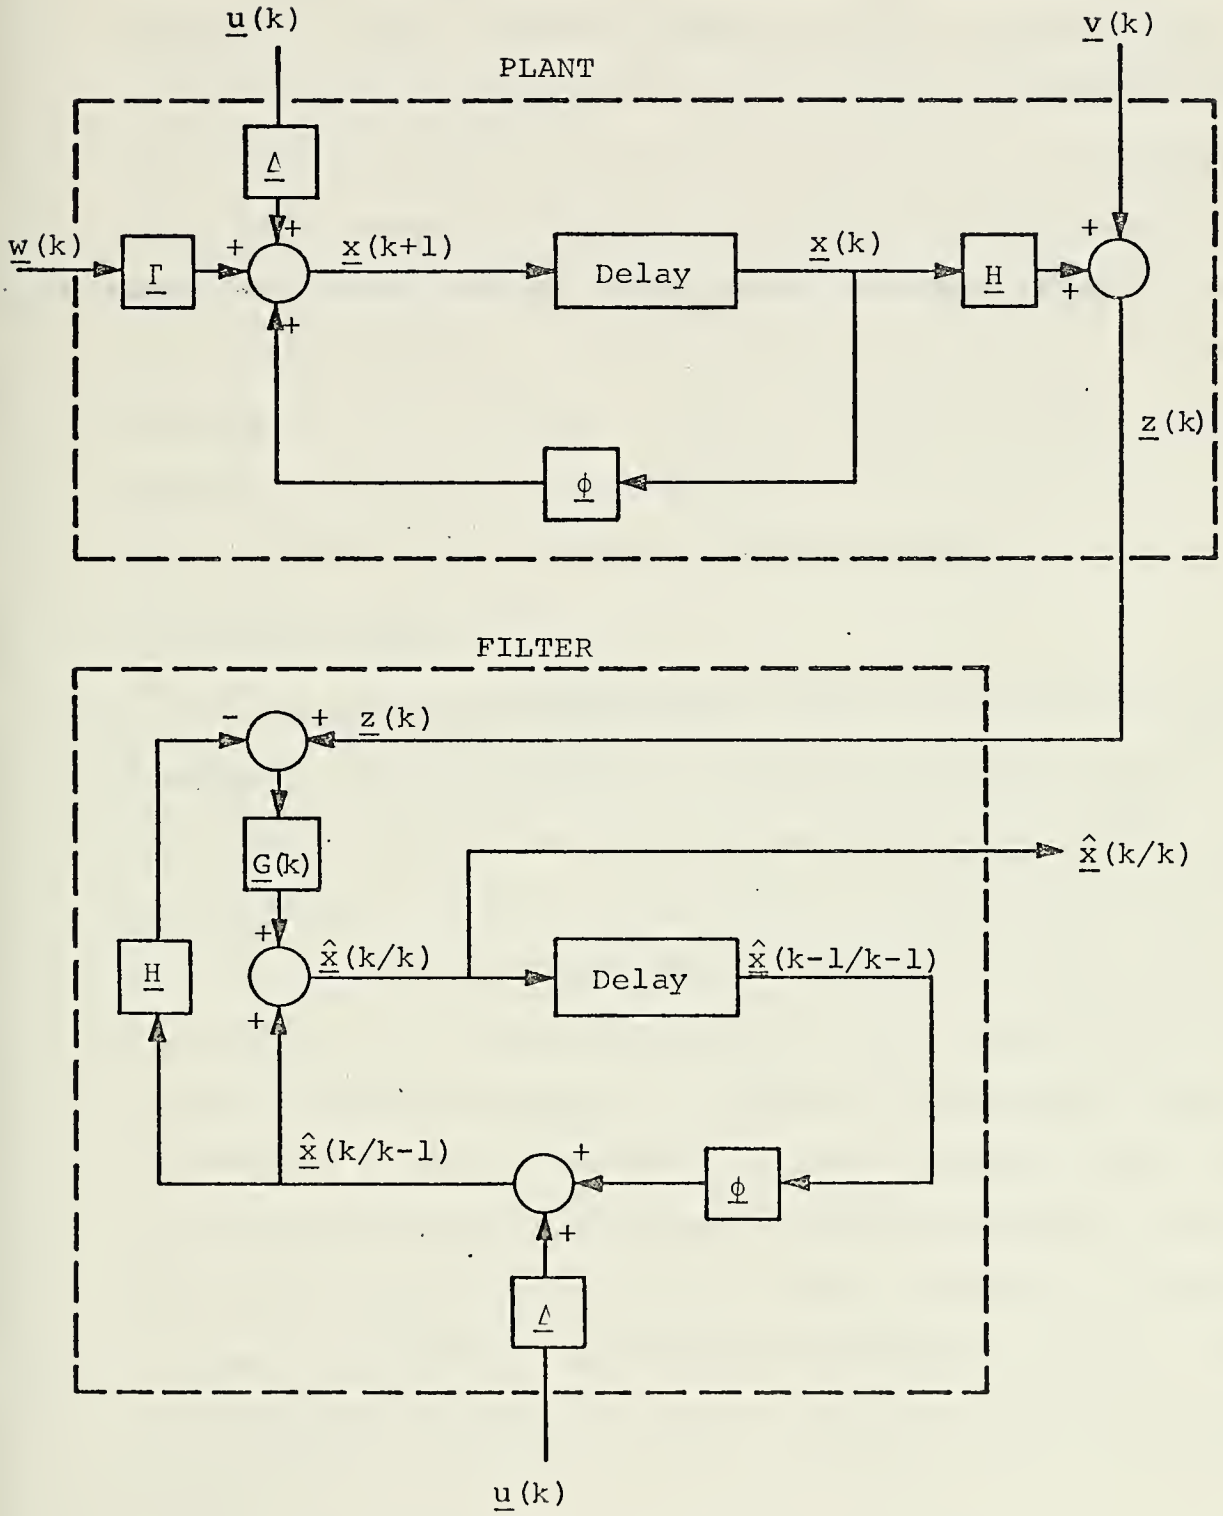

Figure 1. Block Diagram of the Discrete Plant and Kalman Filter.

and predicts ahead what the system states should be based on the state transition matrix, $\underline{\phi}$, and any known deterministic forcing $\underline{u}$. When a new measurement becomes available for current state estimation the filter takes the predicted state vector from the previous iteration, $\hat{\underline{x}}(k/k-1)$, and corrects it by some amount depending on the difference between the predicted vector and the measurement vector. Normally the amount of correction is a fraction (less than one) of the difference and is defined by the gain matrix, $\underline{G}(k)$, which has been calculated using equations (10) - (12) so that the state estimates yield minimum variance estimates.

B. SYSTEM MODELS

In order to apply the Kalman filter to a given situation a model for the plant must be specified. In the case of a fire control system the plant is defined as the target. The motion of the target is characterized by quantities such as position, velocity, acceleration, acceleration rate, etc.

For most applications the plant can be approximated as either a constant-velocity or constant-acceleration target. In terms of a three-dimensional tracking problem with filtering in an orthogonal coordinate system the resultant state vector for the constant-velocity model includes six states --three for position definition and three for velocity. The constant-acceleration model also includes three acceleration states.

In this thesis, for example, the filtering is done in an XYZ Cartesian coordinate system, shown in Figure 2, using

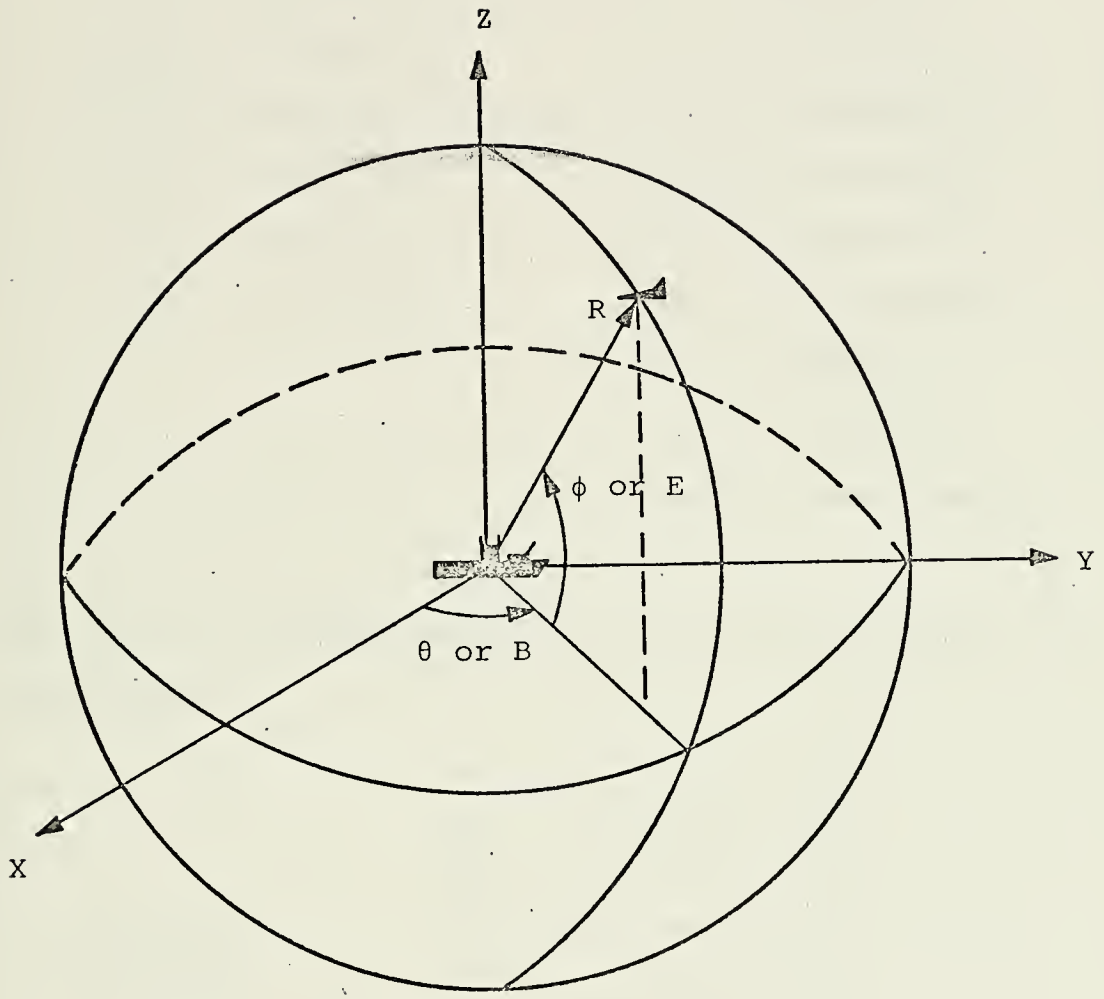

Figure 2. Coordinate System.

both constant-velocity and constant-acceleration models with the resultant state vectors

Constant-velocity Model		Constant-Acceleration Target	
x_1	x position	x_1	x position
x_2	x velocity	x_2	x velocity
x_3	y position	x_3	x acceleration
x_4	y velocity	x_4	y position
x_5	z position	x_5	y velocity
x_6	z velocity	x_6	y acceleration
		x_7	z position
		x_8	z velocity
		x_9	z acceleration

The state transition matrices, $\underline{\phi}$, for the two models are shown below

Constant-Velocity

$$\underline{\phi} = \begin{bmatrix} 1 & T & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & T & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & T \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{17}$$

Constant Acceleration $\underline{\Phi} =$

$$\begin{bmatrix} 1 & T & \frac{T^2}{2} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & T & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & T & \frac{T^2}{2} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & T & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & T & \frac{T^2}{2} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & T \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{18}$$

For the models used in defining the plant in this thesis the deterministic and non-deterministic forcing terms, $\underline{\Delta}\ \underline{u}(k)$ and $\underline{\Gamma}\ \underline{w}(k)$, are assumed to be zero.

C. MONTE-CARLO SIMULATION

The basic premise upon which computer simulation is justified is that the model used for study accurately portrays the phenomenon as it occurs in practice. In order to assure that this requirement is satisfied repeated independent experiments yielding classical random-sample statistics are necessary. The requirement as it applies to actual simulation exercises implies that those parameters in the model that are variable require alteration in a random manner dictated by the expected randomness in practice.

Monte-Carlo evaluation is the process of satisfying the need for randomness in some of the model parameters and is especially applicable with computer simulation where the

necessary calculating capacity and speed is available. Further discussion of Monte-Carlo techniques and applications may be found in [2].

The following discussion presents the necessary information for deciding how many Monte Carlo runs, or iterations, are required to satisfy some desired statistical confidence in the simulation. The source of theoretical information against which empirical sampling of available random number generators are compared is [3].

The use of available random number generators, such as GAUSS or NORMAL for normally distributed random numbers, is the most straightforward method for obtaining the desired randomness to introduce into the simulation. Two factors that must be considered in evaluating the performance of a random number generator are (1) the statistics of the empirical samples compared with the desired statistics and (2) the confidence for which the results of (1) are guaranteed.

For the type of random numbers needed with the Monte-Carlo simulation of the filtering process in a fire control system the merit of acceptance is based on the actual mean and standard deviation (or variance) of the normally distributed random numbers compared to the desired, or specified, values of these quantities. Considering the mean of the distribution first, several variables can be defined that are used in calculating a desired number of samples to achieve an acceptable mean. These include

d - a margin of acceptable error of the sample mean expressed as a percentage of the desired standard deviation, such as 0.1 (10% of the standard deviation),

α - the risk involved in the result, also signifying (100 - α) per cent confidence in the result,

β - defined as (1 - $\alpha/2$).

Entering Figure 3 with the value of β the variable t is defined. The number of samples necessary to give a sample mean within d of the desired mean with a known risk of α is given by

$$n = \frac{t^2\sigma^2}{d^2} \tag{19}$$

It can be seen that if d is expressed as a percentage of σ, the actual value of the standard deviation is not required to solve for the number of samples needed.

To determine the number of samples necessary for desired statistics of the standard deviation refer to Figure 4. Here again, the margin of acceptable error is expressed as a percentage of the standard deviation, and this percentage is the parameter P scaled along the abscissa. The ordinate is labeled "degrees of freedom" and represents the number of samples needed to achieve the various confidences plotted as bars across the graph.

Working through an example shows how the curves are used. Suppose it is desired to execute enough Monte-Carlo runs to assure 90% confidence in sample statistics having an actual mean and an actual standard deviation within 10% of its desired value. Considering the mean first:

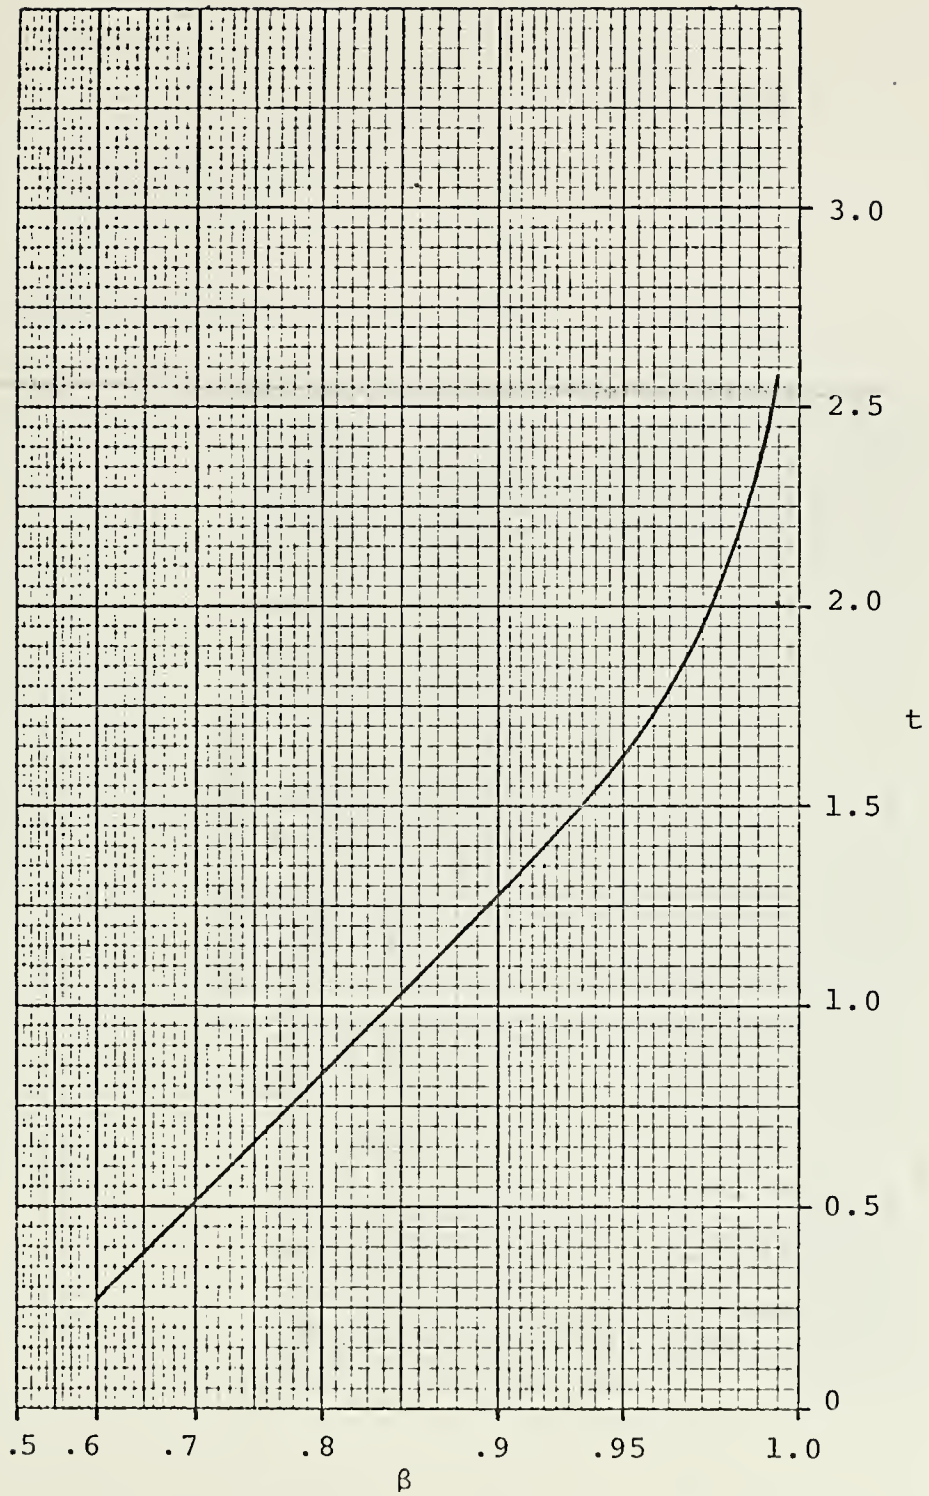

Figure 3. t - β Diagram.

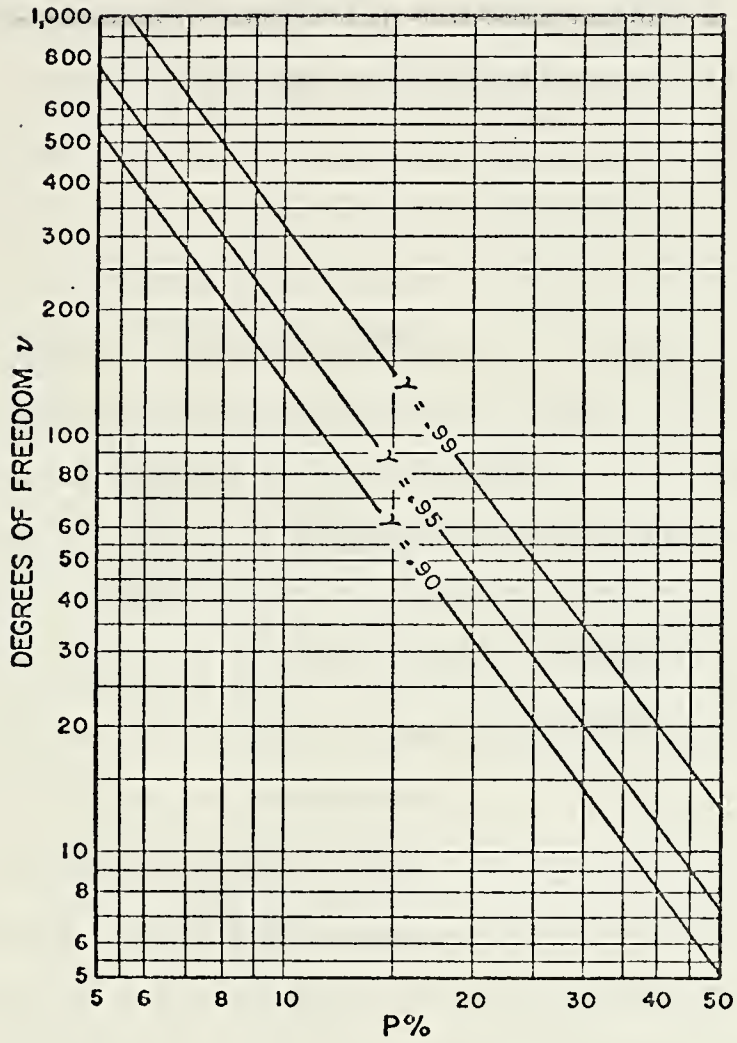

Figure 4. Number of Samples Required to Estimate the Standard Deviation within P Percent of Its True Value with Confidence Coefficient γ.

$$\beta = 1 - \frac{\alpha}{2} = 1 - \frac{.1}{2} = .95 \ . \qquad (20)$$

From Figure 3 the value of t is found to be 1.645, and

$$n = \frac{(1.645)^2\sigma^2}{(.1)^2\sigma^2} = 270 \ . \qquad (21)$$

Referring to Figure 4 to find the number of samples required for the desired standard deviation results gives n = 140. Therefore, in order to satisfy all restrictions 270 samples would be required.

Verification of these theoretical results involved sampling two subroutines available in the NPS Computer Facility Sublibrary, GAUSS and NORMAL. The approach used was to sample each number generator for 1000 ensembles of several numbers of samples in each ensemble. The number 1000 was chosen to obtain steady-state values in the statistics determined for the runs of length 50, 75, 100, 150, 200, 500, 700, 1000, and 5000 samples each. A summary of the results is included as Table I,[1] and the FORTRAN program for the study may be found in Appendix A.

It may be noted in Table I that the results for the normally distributed random number generator GAUSS are incomplete, and this is a consequence of the substantially greater execution time required than for NORMAL. Whereas NORMAL used

---

[1]Theoretical results are limited in accuracy to one's ability to read Figure 3. Also, percent of standard deviations within criteria of desired standard deviations are not shown for theoretical calculations because (1) Figure 4 is not complete and (2) the limiting factor in satisfactory M-C simulation is the satisfaction of requirements for the mean, not for the standard deviation.

TABLE I

COMPARISON OF EMPIRICAL AND THEORETICAL
NORMALLY DISTRIBUTED RANDOM NUMBERS

Note (a) - Percent of Means within percent criteria of desired standard deviation

Note (b) - Percent of Standard Deviations within same percent criteria as (a)

approximately 25 minutes of execution time to carry out the entire analysis, GAUSS required 90 minutes to evaluate up through 700 sample ensemble runs. For this reason NORMAL is recommended when normally distributed random numbers are desired.

III. DEVELOPMENT OF MONTE-CARLO SIMULATION PROGRAM (MCSP)

A. TRACK MODEL

In order to provide realistic data for testing filter performance against an airborne target it was necessary to develop a model based on a conventional dive bomb approach by a modern aircraft against a seaborne target. From knowledgeable sources the parameters of such an approach were obtained and, in accordance with the 4-Hz sampling rate of the radar, used to develop a simulation including such features as a constant-acceleration dive, a pull-out following ordinance release, and evasive maneuvers while withdrawing in a gradual climb. The individual segments of the 233-point track will be discussed as well as the methods one may use to develop other tracks.

While in actual operation a radar measures range, bearing, and elevation (RBE), and perhaps rates as well, convenience dictated development of the track in an XYZ coordinate system centered at the ship, or radar,[2] as shown in Figure 2. Such parameters as ship's speed, bearing, roll, pitch, etc. were not considered in the simulation to avoid model complexity. These quantities, while offering potential sources of error to any overall tracking system, were avoided to concentrate on the filter performance and not the various correction factors applied to input measurement data.

[2]The radar and the gun are assumed to be at the center of the ship, or origin of coordinate system, and at sea level.

Satisfying the requirement for randomness in the track data points, the variable factors mentioned earlier for Monte-Carlo simulation, involved, when using one basic track, the addition of randomly distributed Gaussian measurement noise to every point. An alternative approach might have been to run the simulation with many independent tracks randomly distributed about the expected track, but this would have caused much additional complexity and increased execution time in the simulation.

In order to realistically generate noisy measurements the track's XYZ data points, after being read by the Monte-Carlo Simulation Program (MCSP), are converted to RBE, the desired Gaussian measurement noise with zero mean and appropriate standard deviation is added to each data point, conversion back into the same XYZ coordinate system takes place, and the data is available as simulated coordinate-converted output from the radar ready for analysis.

The original track is layed out with the aircraft approaching from the +X direction with initial radar contact initiated at a range of 7200 yards and altitude of 4333 yards. Its initial velocity is approximately 250 knots, and in the scenario of the attack has just climbed to the given altitude from a low or medium level approach in preparation for the dive phase of the attack. A summary of the track segments follows:

Track Points	Segment Description	G Turn	Comments
1 - 33	Initial Dive	1	Assumes 40° Dive Angle
34 - 113	Accelerating Dive	-	139.16 yd/sec-249.75 yd/sec
114 - 137	Pullout	4	To altitude of 958 yards
138 - 141	Starboard Turn	2	
142 - 145	Port Turn	2	
146 - 149	Port Turn	2	
150 - 157	Port Turn	3.5	Begin 10° Climb -
158 - 165	Starboard Turn	3.5	Velocity of 249.76
166 - 173	Port Turn	3.0	yd/sec is maintained
174 - 181	Starboard Turn	3.0	
182 - 193	Port Turn	3.0	
194 - 205	Starboard Turn	2.5	
206 - 221	Port Turn	2.5	
222 - 233	Starboard Turn	2.0	

Note that the port turn at points 142 - 145 is followed by another similar turn from points 146 - 149. The need for the additional segment rather than creating just one turn from points 142 - 149 will become clear later in the discussion.

The geometric relationships used to translate the desired track into mathematical terms include both basic, intuitive approaches and some requiring direct application to a given target orientation. These general techniques will now be discussed; the implementation of the particular track segments in a FORTRAN program may be found in Appendix B.

The following sub-sections portray the various possible maneuvers and track orientations used in developing the track for the MCSP.

A.1 The initial conditions include the starting point anywhere in the coordinate system with the velocity vector parallel to an axis. Specified parameters for a turn can include angle of turn, time of execution, tangential velocity,

constant radial acceleration, and final translation with respect to starting point. (Examples are: Points 1 - 33, 138-141, 146 - 149)

The geometrical arrangement is shown in Figure 5, and the following pertinent definitions and equations apply: a is the radial acceleration, vel is the tangential velocity, and T is the time of maneuver; thus

$$a = \frac{32.2}{3} \text{ yds/sec}^2 \cdot G \text{ of turn} = \text{vel}^2/R \ , \tag{22}$$

$$C = (4h(2R-h))^{\frac{1}{2}}, \ S = R\theta = 2R\sin^{-1}C/2R,$$

$$T = S/2 \cdot \text{vel} \ . \tag{23}$$

Using the pertinent equations certain parameters of the turn can be specified while assuring that the other parameters are reasonable. This results in values for R, θ, and the number of track points in the segment and provides incrementally growing $\Delta\theta$'s. Then each new track point is given by

$$X_n = X_o \pm R \sin \Delta\theta \tag{24}$$

$$Y_n = Y_o \pm (R - R \cos \Delta\theta) \ . \tag{25}$$

Note: The optional signs above are dependent upon the orientation of the maneuver on the axes.

A.2 The initial conditions include the starting point anywhere with the velocity vector at some angle, τ, with respect to an axis. The turn is in the plane of two of the axes with certain parameters known, such as those mentioned in the previous sub-section. Four types of turn are possible in this scenario:

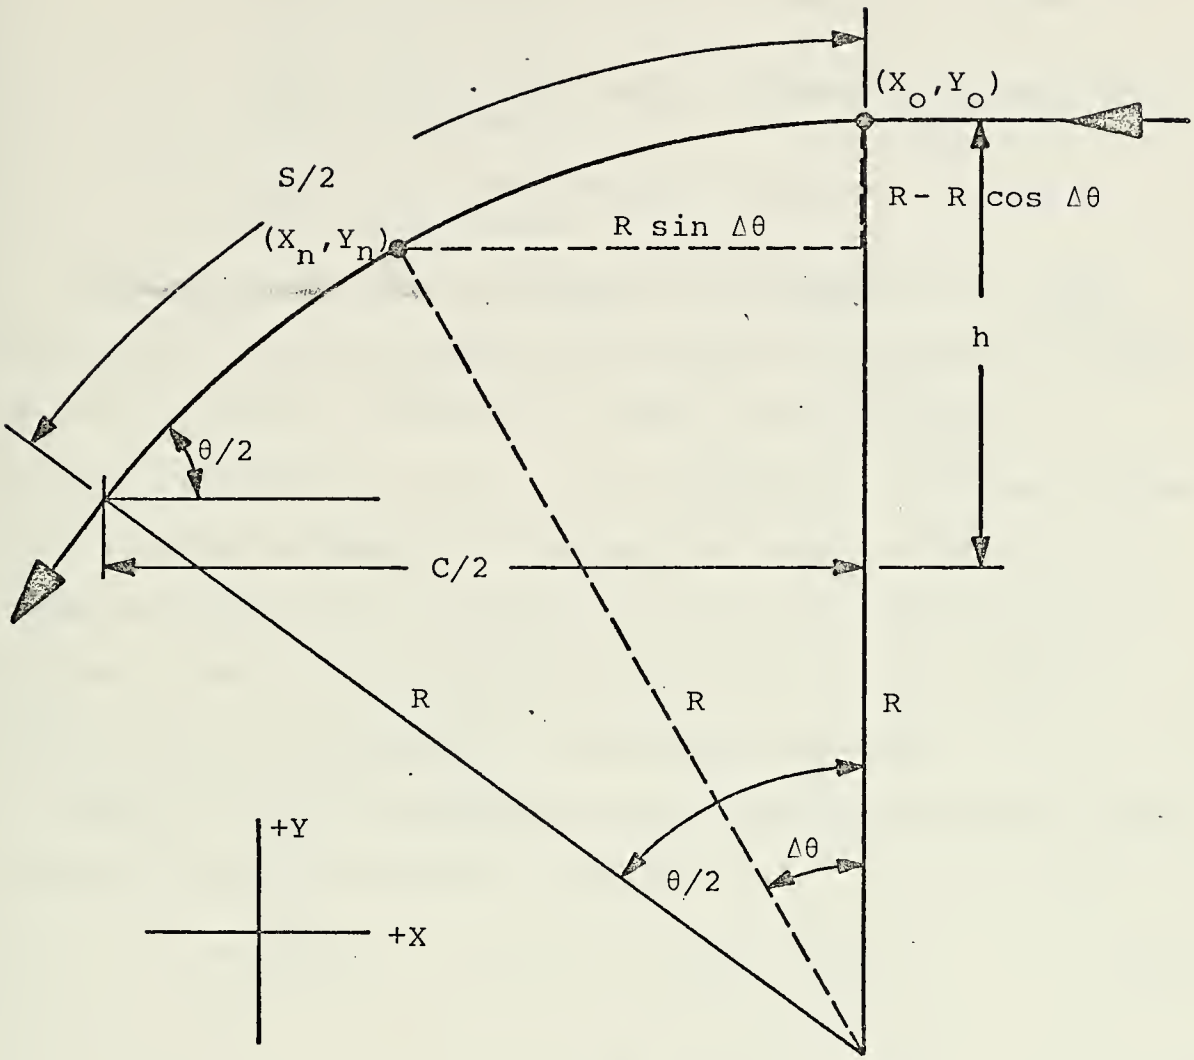

Figure 5. Geometry for Turn with Velocity Vector Initially Parallel to Axis.

a - Initial velocity vector τ degrees to right of axis; right turn,

b - Initial velocity vector τ degrees to right of axis; left turn,

c - Initial velocity vector τ degrees to left of axis; right turn,

d - Initial velocity vector τ degrees to left of axis; left turn.

The same pertinent equations as presented in A.1 are valid here, and the geometrical layouts are shown in Figures 6 and 7. Figure 6 applies to cases a and d above, and Figure 7 to cases b and c. For comparison all cases will be based on the assumption of an initial velocity vector at τ degrees with respect to the X axis and the turn in the XY plane. However, the procedure is directly applicable to other axes and planes with similar orientation.

The following development for obtaining the desired quantities $\Delta\phi$ and C' applies to Figure 6.

$$\alpha = \frac{180-\Delta\theta}{2}, \quad \lambda = \beta-\alpha, \quad \beta = 180 - (\tau+\Delta\theta) \tag{26}$$

$$\therefore\lambda = 180 - \tau - \Delta\theta - 90 + \frac{\Delta\theta}{2} = 90 - \tau - \frac{\Delta\theta}{2} \tag{27}$$

and $$\Delta\phi = 90 - \lambda = \tau + \frac{\Delta\theta}{2} \tag{28}$$

Also, it can be seen that $C' = 2\ R \sin(\Delta\theta/2)$.

Similarly, the following development applies to Figure 7.

$$\alpha = \frac{180-\Delta\theta}{2}, \quad \beta = 90 + (90-\tau) = 90 - \frac{\Delta\theta}{2} \tag{29}$$

$$\Delta\phi = \beta - \alpha = 180 - \tau - 90 + \frac{\Delta\theta}{2} = 90 - \tau + \frac{\Delta\theta}{2} \tag{30}$$

Again, it can be seen that $C' = 2\ R \sin(\Delta\theta/2)$.

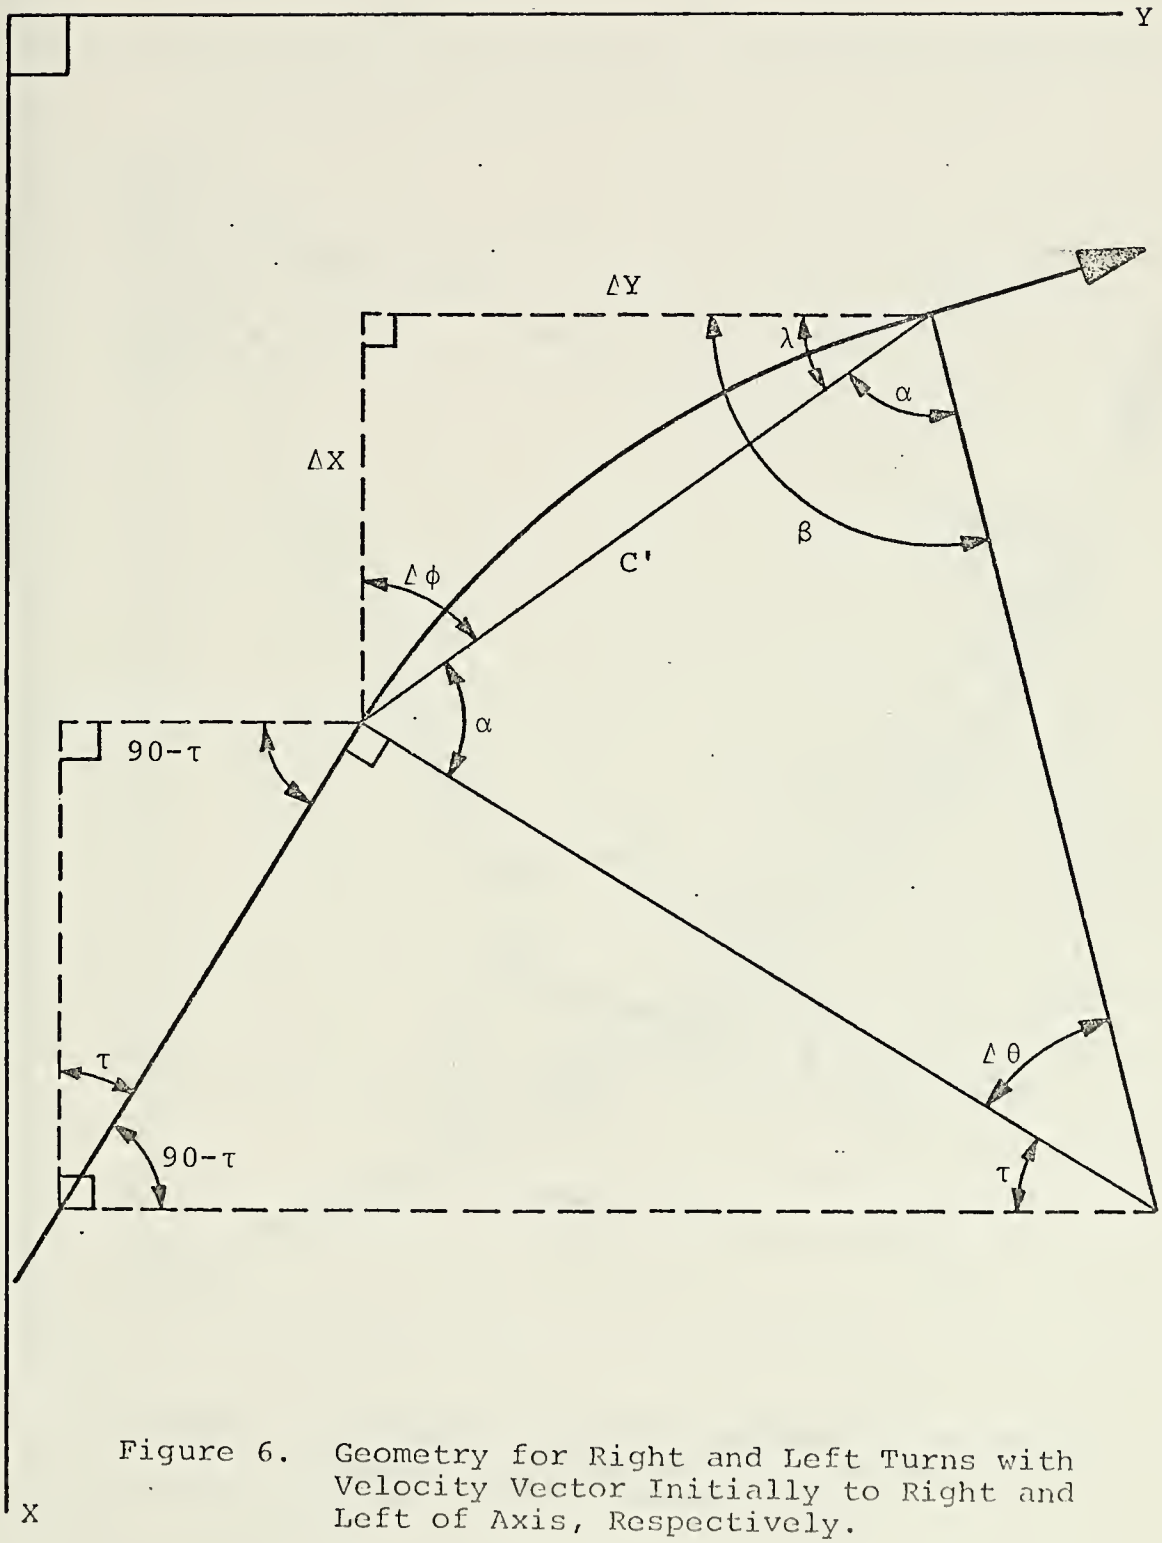

Figure 6. Geometry for Right and Left Turns with Velocity Vector Initially to Right and Left of Axis, Respectively.

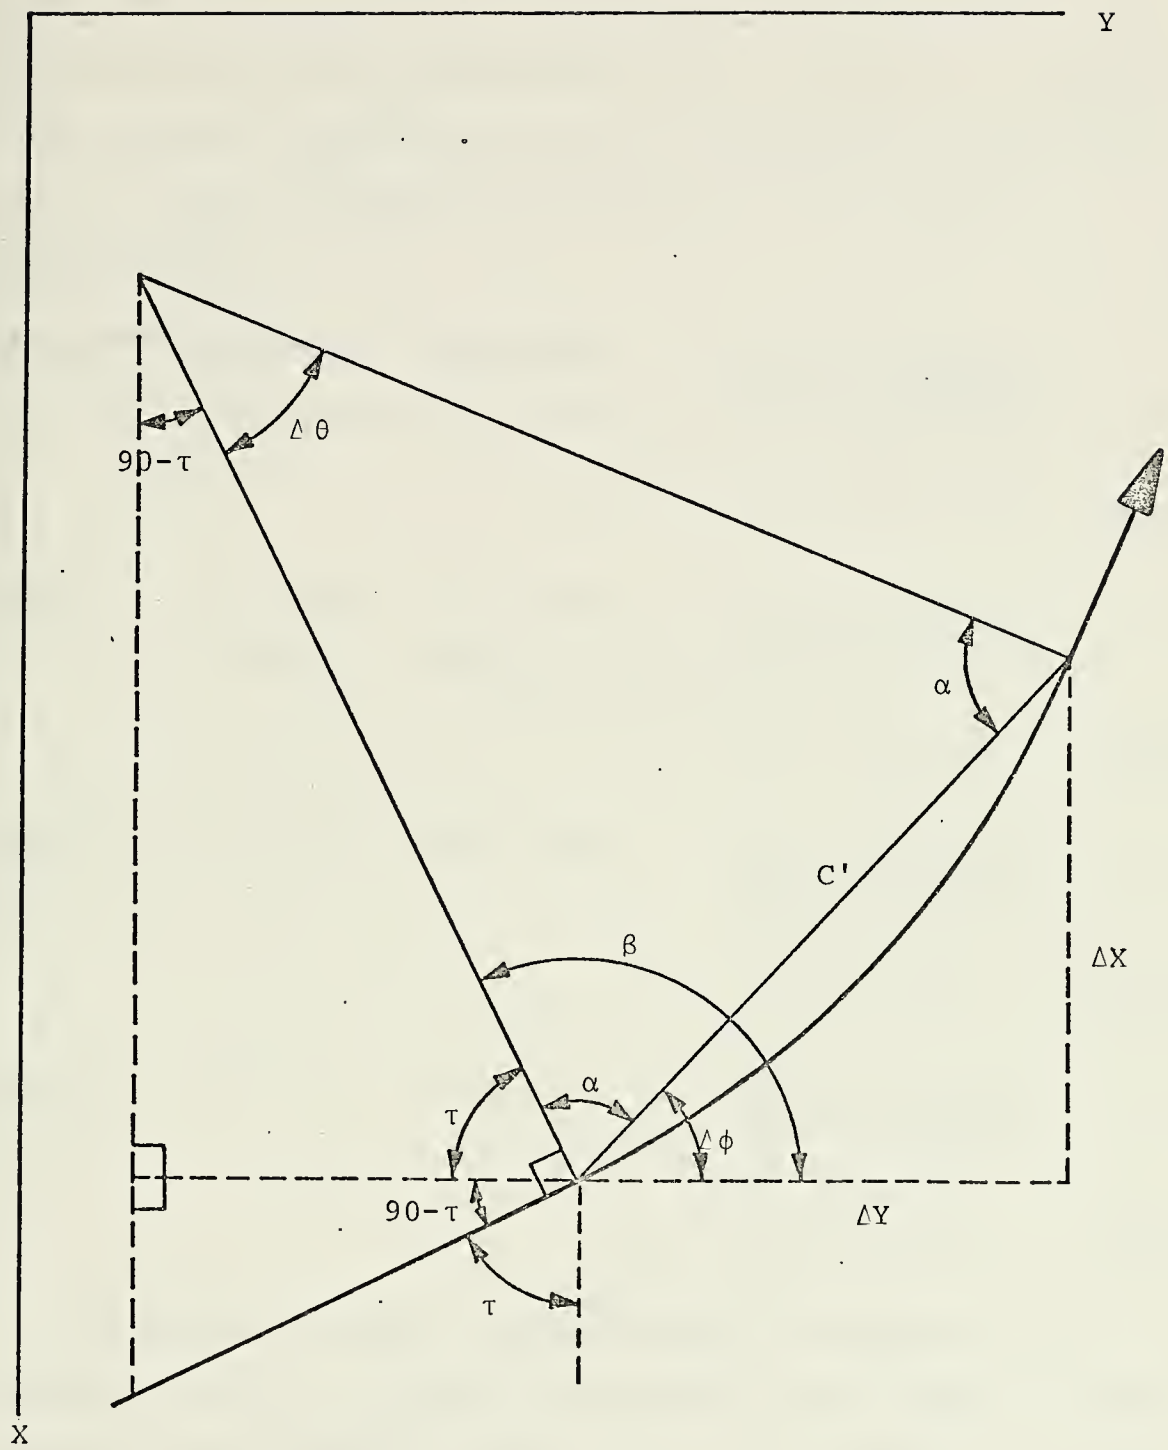

Figure 7. Geometry for Right and Left Turns with Velocity Vector Initially to Left and Right of Axis, Respectively.

Given that the quantities $\Delta\phi$ and C' are available (depending upon the choice of the variable parameters) the track points can be generated for the four cases. A summary for the four cases follows with the appropriate figures for a, b, c, and d included as Figures 8, 9, 10, and 11, respectively.

A.2.a τ to right - right turn

(Example: Points 114-137)

$$\Delta X = C' \cos \Delta\phi$$
$$\Delta Y = C' \sin \Delta\phi$$
$$X_n = X_o - \Delta X$$
$$Y_n = Y_o + \Delta Y \qquad (31)$$

A.2.b τ to right - left turn

(Example: Points 142-145)

$$\Delta X = C' \sin \Delta\phi$$
$$\Delta Y = C' \cos \Delta\phi$$
$$X_n = X_o - \Delta X$$
$$Y_n = Y_o + \Delta Y \qquad (32)$$

A.2.c τ to left - right turn

$$\Delta X = C' \sin \Delta\phi$$
$$\Delta Y = C' \cos \Delta\phi$$
$$X_n = X_o - \Delta X$$
$$Y_n = Y_o - \Delta Y \qquad (33)$$

A.2.d τ to left - left turn

$$\Delta X = C' \cos \Delta\phi$$
$$\Delta Y = C' \sin \Delta\phi$$
$$X_n = X_o - \Delta X$$
$$Y_n = Y_o - \Delta Y \qquad (34)$$

It should be noted that in using this approach it is assumed that when a turn is initiated at some angle, τ, with respect to an axis the quantity $(\tau + \theta)$ is less than or equal to 90 degrees. Otherwise, one must assure that the quantities ΔX and ΔY are added to or subtracted from the initial coordinates correctly. That is, beyond 90 degrees the X or Y

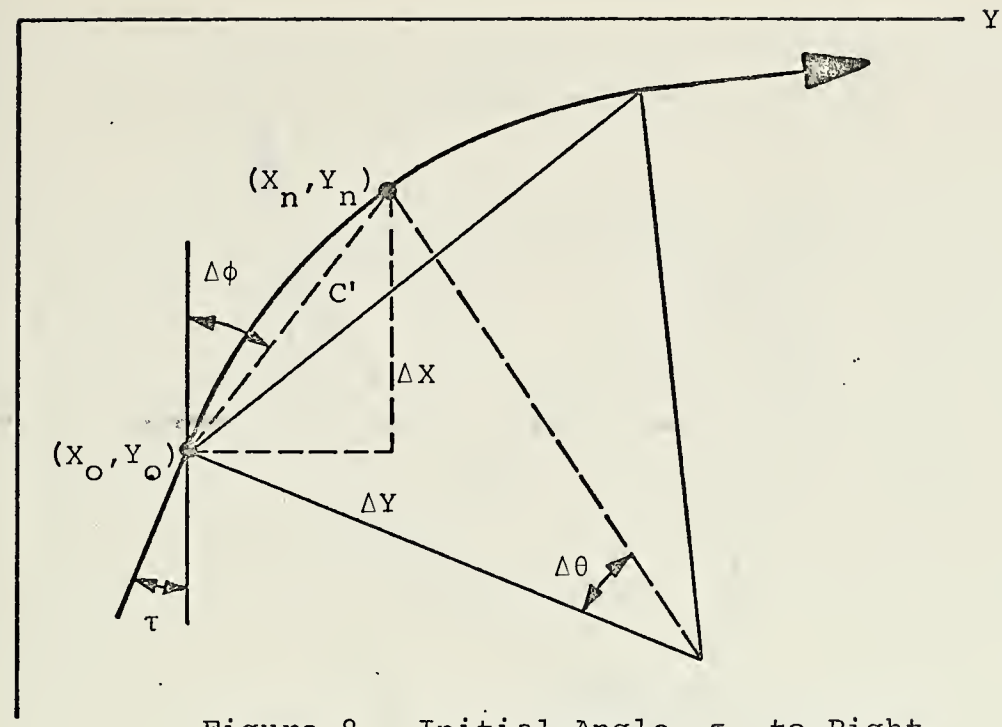

Figure 8. Initial Angle, τ, to Right of Axis - Right Turn.

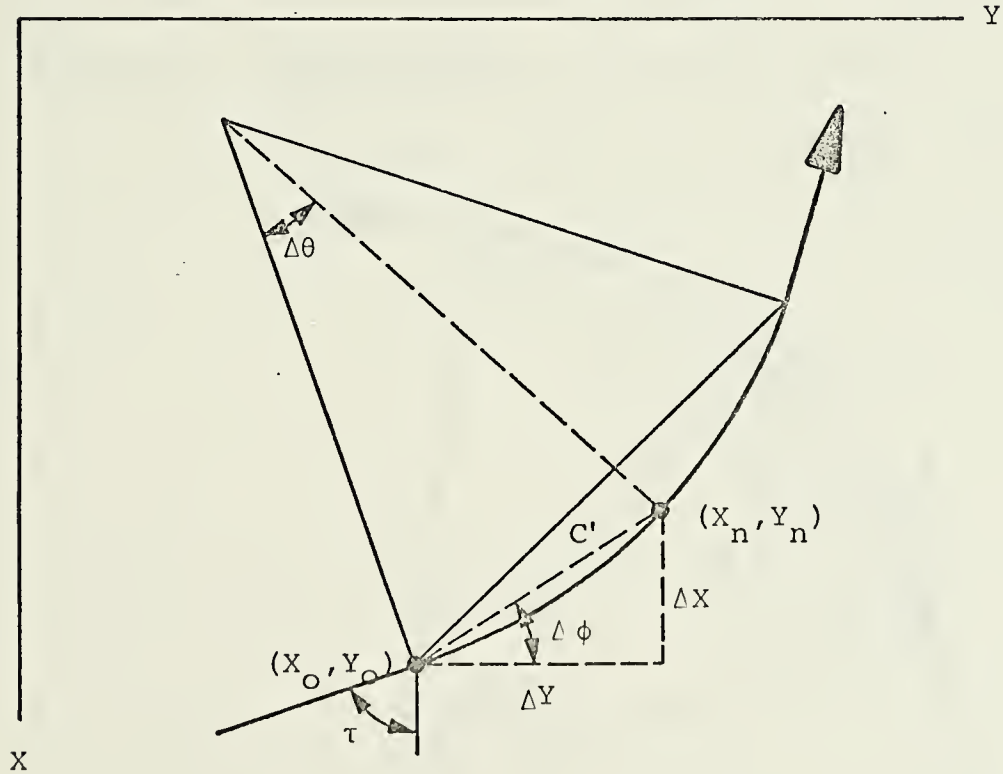

Figure 9. Initial Angle, τ, to Right of Axis - Left Turn.

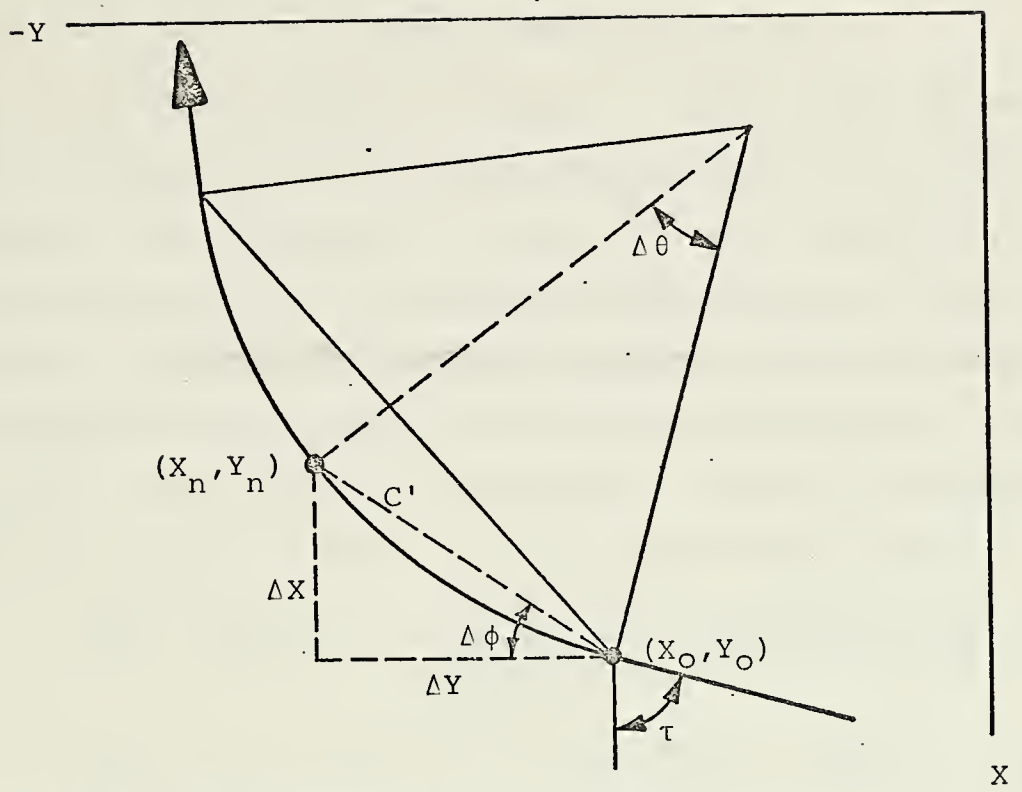

Figure 10. Initial Angle, τ, to Left of Axis - Right Turn.

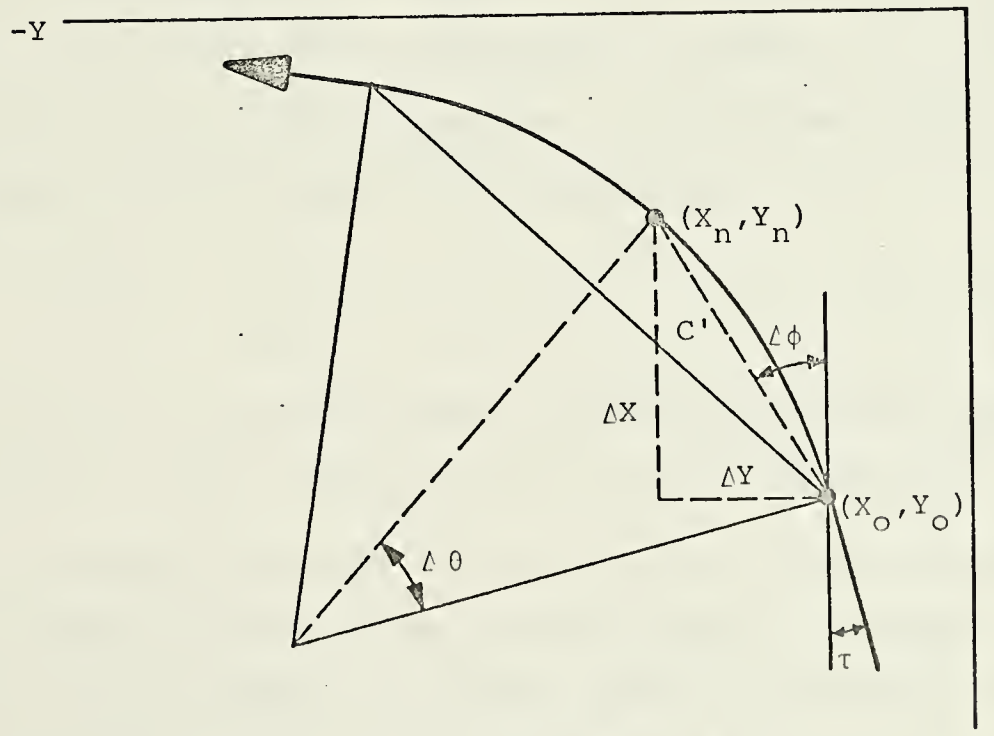

Figure 11. Initial Angle, τ, to Left of Axis - Left Turn.

coordinates may begin to change in directions opposite to that discussed in the scenario described above.

A.3 Initial conditions include a starting point anywhere in the coordinate system with constant-acceleration motion in a straight line. (Example: Points 34 - 113) Specified parameters may include initial and final velocity, time of execution, acceleration (assumed constant), angle of segment with respect to some plane, and final translation from starting point. The geometric arrangement is shown in Figure 12, and the pertinent kinematic relationships follow below

$$\text{Final Velocity} = \frac{2 \cdot S}{\left(\text{Time of Execution}\right)} - \text{Initial Velocity}, \quad (35)$$

$$\text{Final Vel.} = \text{Init. Vel.} + \text{Acceleration} \cdot \text{Time}, \quad (36)$$

$$Z \text{ Translation} = S \cdot \sin \alpha, \quad (37)$$

$$X \text{ Translation} = S \cdot \cos \alpha, \quad (38)$$

$$S = \tfrac{1}{2} (\text{Init. Vel.} + \text{Final Vel.}) \cdot \text{Time} . \quad (39)$$

Using these equations to define a track segment, the incremental displacements can be defined as:

$$\Delta X = \Delta S \cdot \cos \alpha, \quad (40)$$

$$\Delta Z = \Delta S \cdot \sin \alpha . \quad (41)$$

Then each point along the track is defined by applying these incremental changes relative to the previous track point.

A.4 The last situation to be discussed is that applying to the evasive retreat of the aircraft from the seaborne target. In this scenario a gradual climb is initiated after passing over the ship, and the climb angle of β degrees

requires an additional perspective into the aircraft's motion. Using the techniques discussed previously in subsection A.2 the aircraft's track was defined in the XY plane of the coordinate system. If, however, the incremental Z motion is such as to give a β climb angle the apparent effect in the plane of the aircraft is to cause an increasing radially accelerating turn while maintaining the same constant-acceleration turn in the XY plane. It can be seen in Figure 13 that in the plane of the aircraft the radius of curvature decreases from R_1 to R_2; therefore, the radial acceleration increases as it is inversely related to the radius in a constant velocity model by $R = Vel^2/Acceleration$. This apparent complication is justifiable in the context of actual operation in that an aircraft might, in fact, execute a turn with an increasing amount of radial acceleration. This causes no problems in the simulation as long as the angle, τ, between the appropriate axis and the aircraft's velocity vector is continuously updated in order to correctly initiate the succeeding maneuver.

Two plots of the aircraft motion throughout the entire maneuver are included as Figures 14 and 15. Figure 14 depicts the XZ plane, and Figure 15 shows a top view of the XY plane.

B. TRACK OPTIONS

The groundwork for the track development having been discussed, next follows a description of the options available in using this or any other track in the MCSP. The discussion

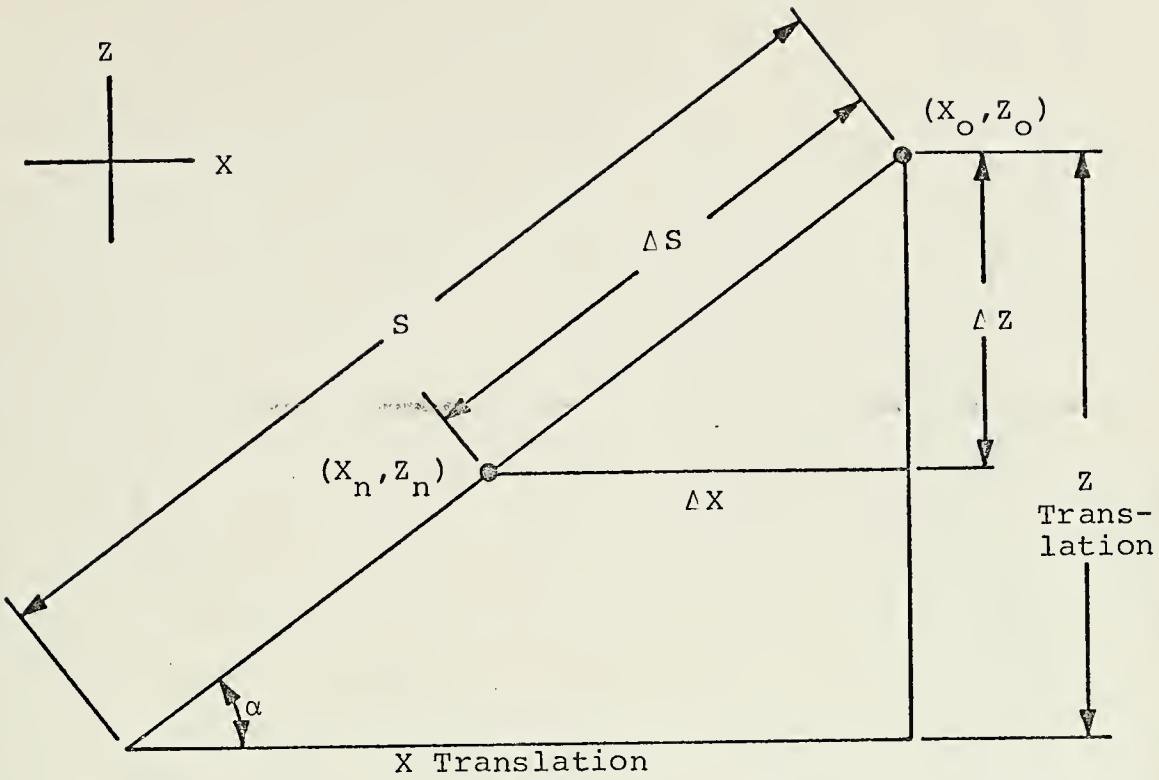

Figure 12. Constant Acceleration Motion in a Straight Line.

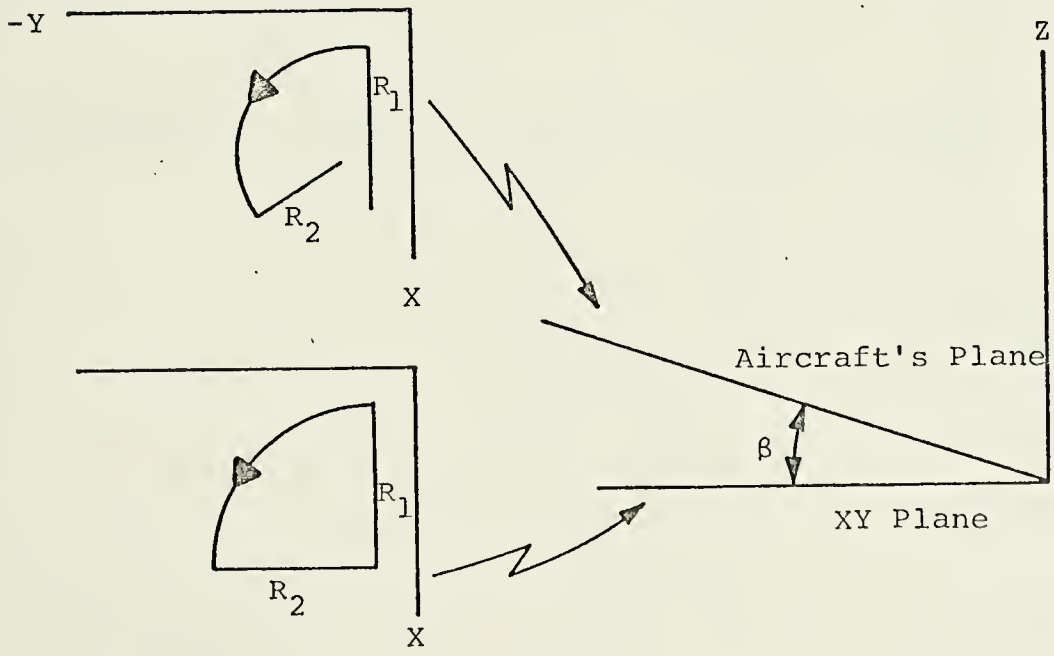

Figure 13. Constant Radial Acceleration Turn with Climb Angle of β.

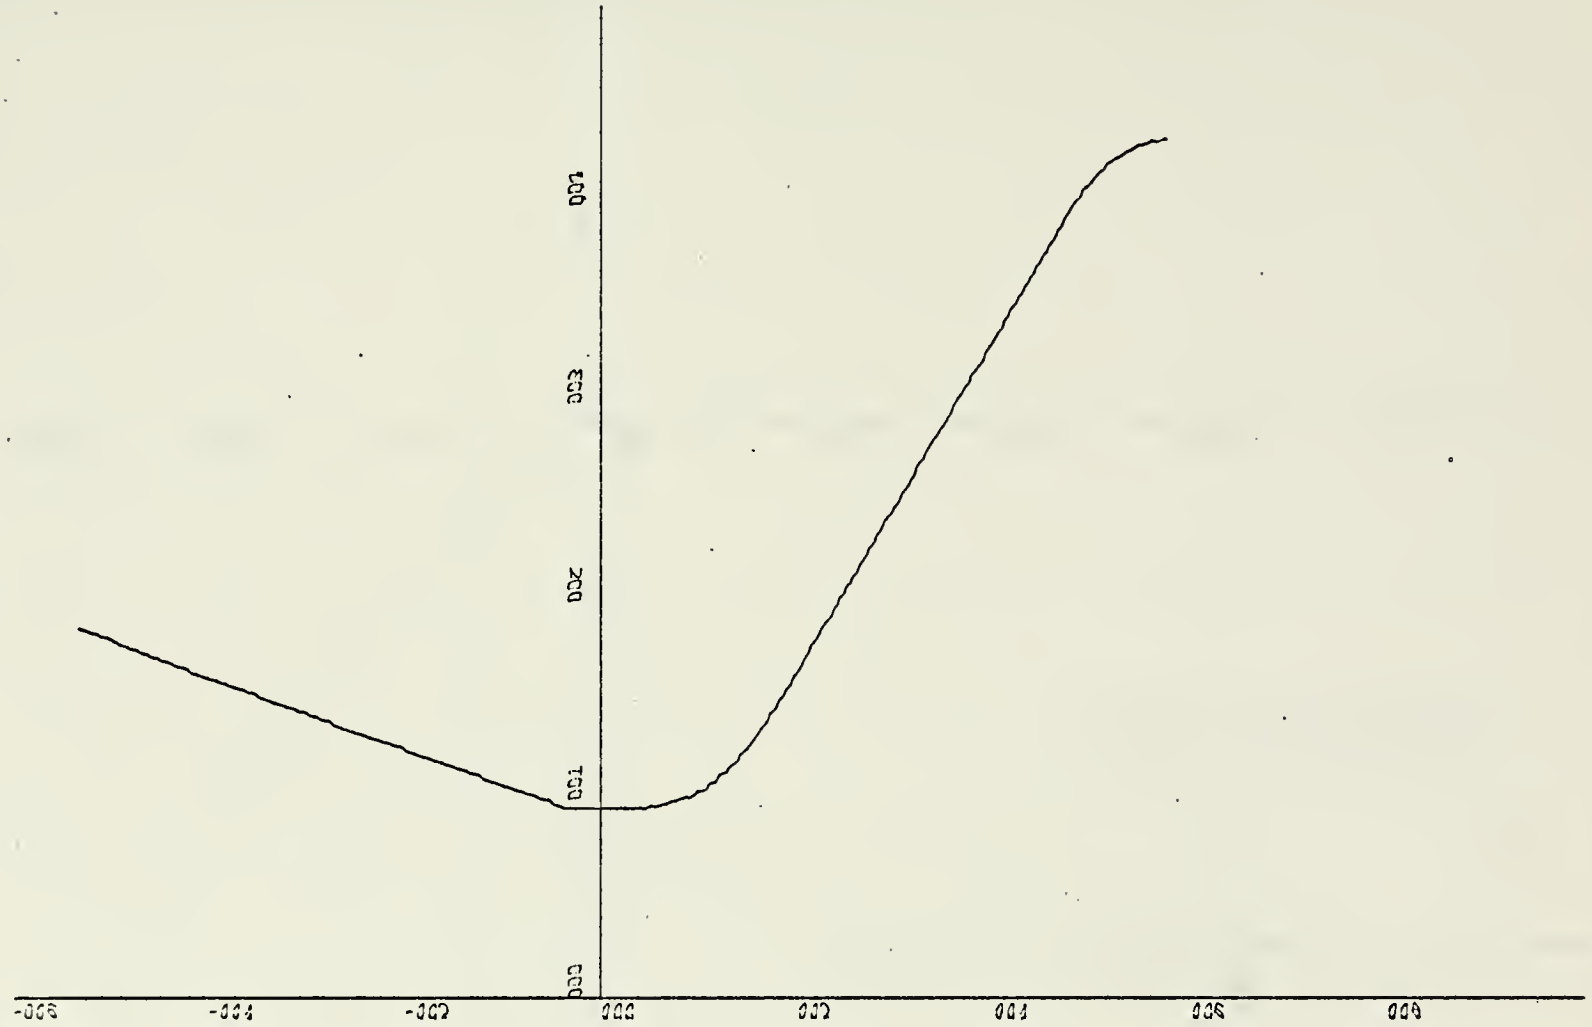
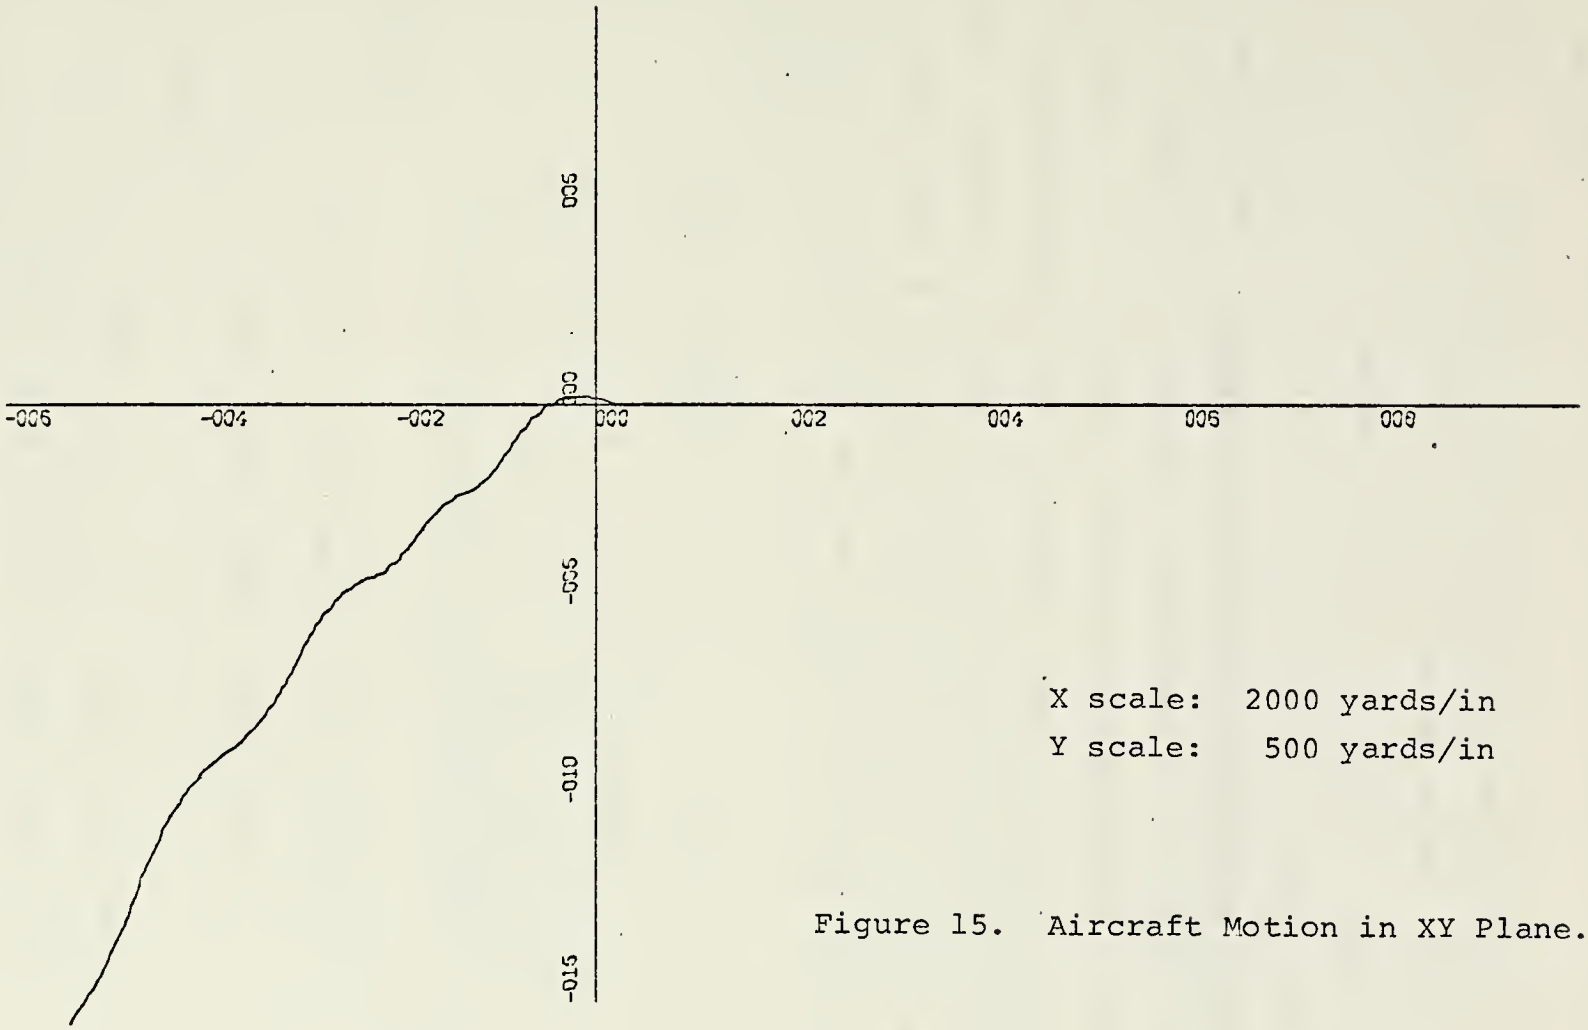


X scale: 2000 yards/in
Z scale: 1000 yards/in

Figure 14. Aircraft Motion in XZ Plane.



X scale: 2000 yards/in
Y scale: 500 yards/in

Figure 15. Aircraft Motion in XY Plane.

of implementing the desired options follows in a later section.

B.1 The first option available is the selection of direction of approach of the airborne target relative to the coordinate system centered at the ship. This rotational capability is achieved by inputing the original track in XYZ coordinates, converting into RBE, and adding a desired radial increment to the bearing coordinate of every point shown in Figure 16. If track velocities are also input to the program (an option that is covered later), it can be seen that the component in the Z direction is not affected while those in the X and Y directions are. Following is a derivation to handle this problem, and the vector presentation is shown in Figure 17.

$$|VEL'| = |VEL| \tag{42}$$

$$\dot{X} = -VEL \cdot \cos \beta \qquad \dot{Y} = VEL \cdot \sin \beta \tag{43}$$

$$\dot{X}' = -VEL' \cdot \cos (\beta-\Delta) = -VEL \cdot \cos (\beta-\Delta) \tag{44}$$

$$\dot{Y}' = VEL' \cdot \sin (\beta-\Delta) = VEL \cdot \sin (\beta-\Delta) \tag{45}$$

Using

$$\cos (\beta-\Delta) = \cos \beta \cos \Delta + \sin \beta \sin \Delta \tag{46}$$

$$\sin (\beta-\Delta) = \sin \beta \cos \Delta - \cos \beta \sin \Delta \tag{47}$$

We have

$$\dot{X}' = -VEL \cdot \cos \beta \cos \Delta - VEL \cdot \sin \beta \sin \Delta \tag{48}$$

$$\dot{Y}' = VEL \cdot \sin \beta \cos \Delta - VEL \cdot \cos \beta \sin \Delta \tag{49}$$

And finally,

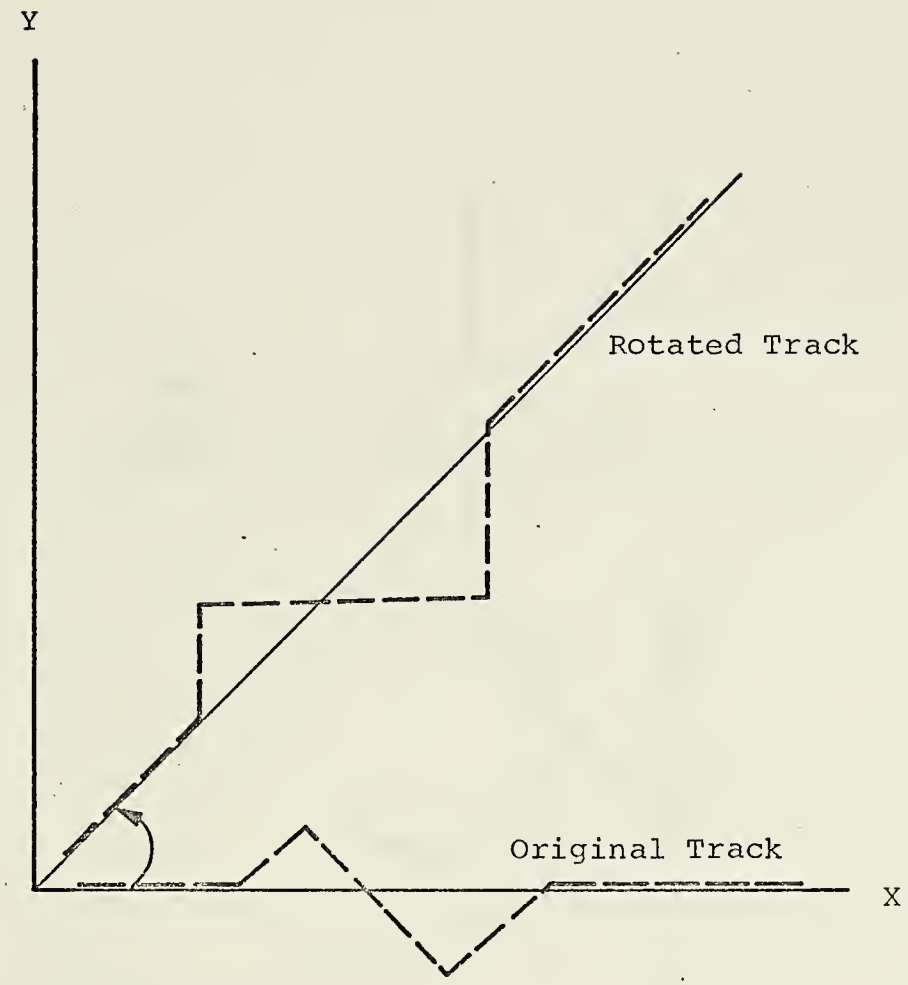


Figure 16. Rotation of Track.

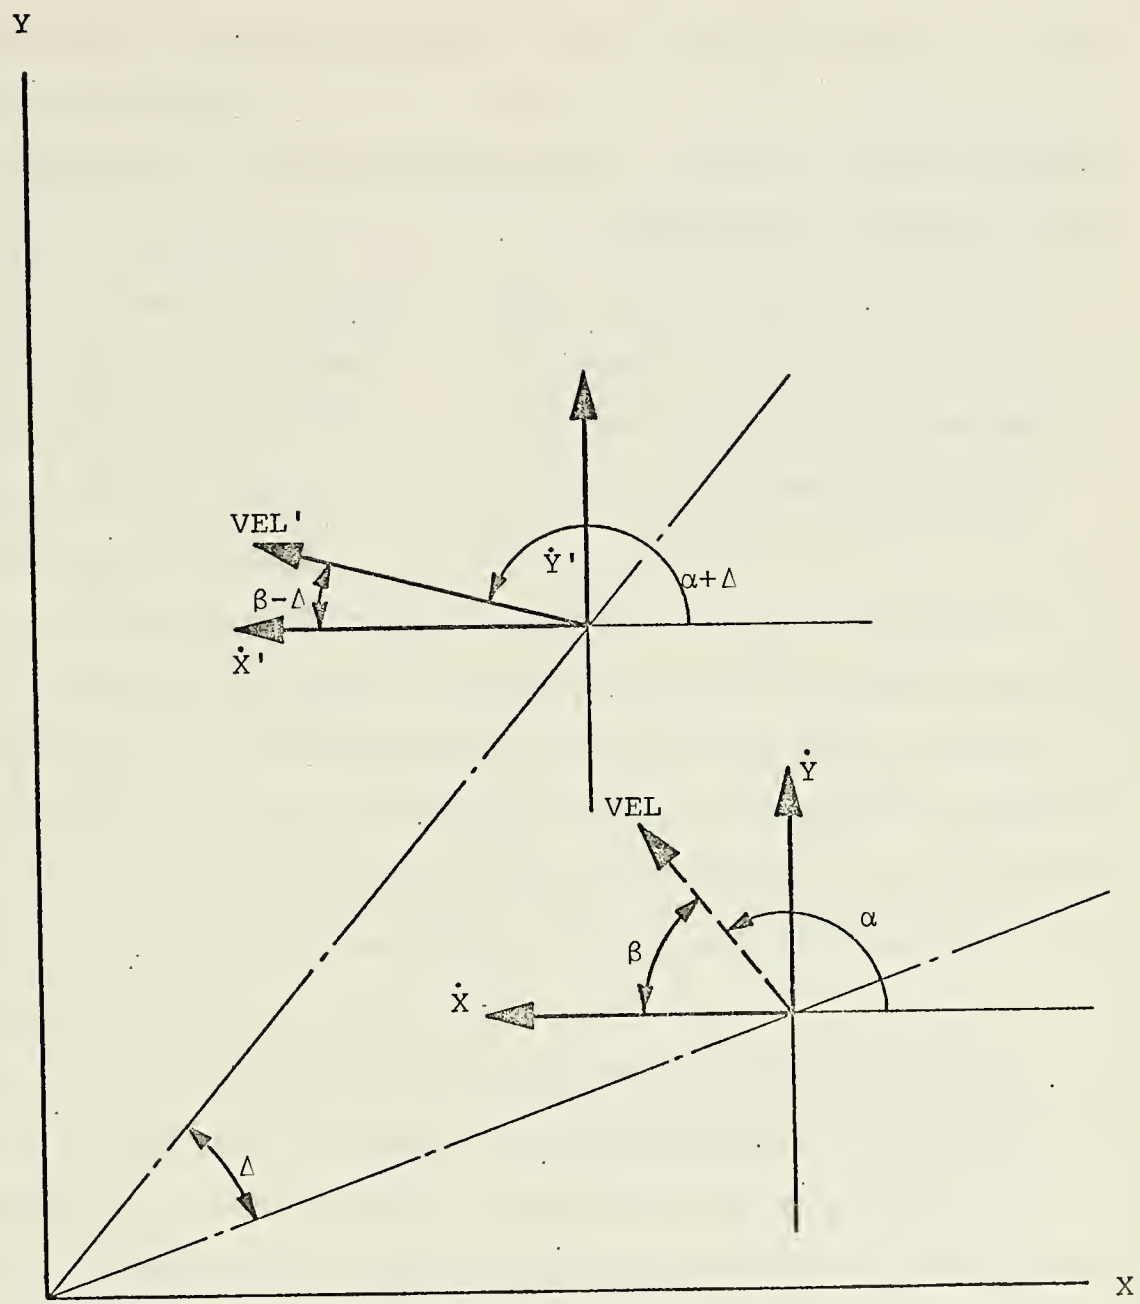

Figure 17. Velocity Vectors for Track Rotation.

$$\dot{X}' = \dot{X} \cos \Delta - \dot{Y} \sin \Delta \quad (50)$$

$$\dot{Y}' = \dot{Y} \cos \Delta + \dot{X} \sin \Delta \quad (51)$$

where $\dot{X}$ and $\dot{Y}$ are the original track velocities and Δ is the angle of rotation.

The MCSP is arranged to provide a choice of the following angles of approach: 0°, 45°, 90°, and 202.5°. If other than these choices is desired the MCSP can be easily altered by referring to the segment of the program several statements after label 13 in the listing of the MCSP included as Appendix C. The variable DEL can be set to the desired radial increment in radians.

B.2 The second option available is the translation of all of the track points by desired amounts for each coordinate axis. The implementation is discussed later, but the method simply involves adding the desired increments to all of the original track points' XYZ coordinates. The velocity components at each track point are not affected by the translation.

B.3 A third option is the choice of adding measurement noise to the track points. If requested, the noise is added to the RBE coordinates and conversion back into noisy XYZ occurs. This noise, as now exists in the MCSP is mean zero, and the user selects the desired standard deviations in range, bearing, and elevation (units are yards, radians, radians).

In conclusion, the procedure for implementation of a track and possible options requires that the XYZ data points be generated offline and read into the MCSP where various

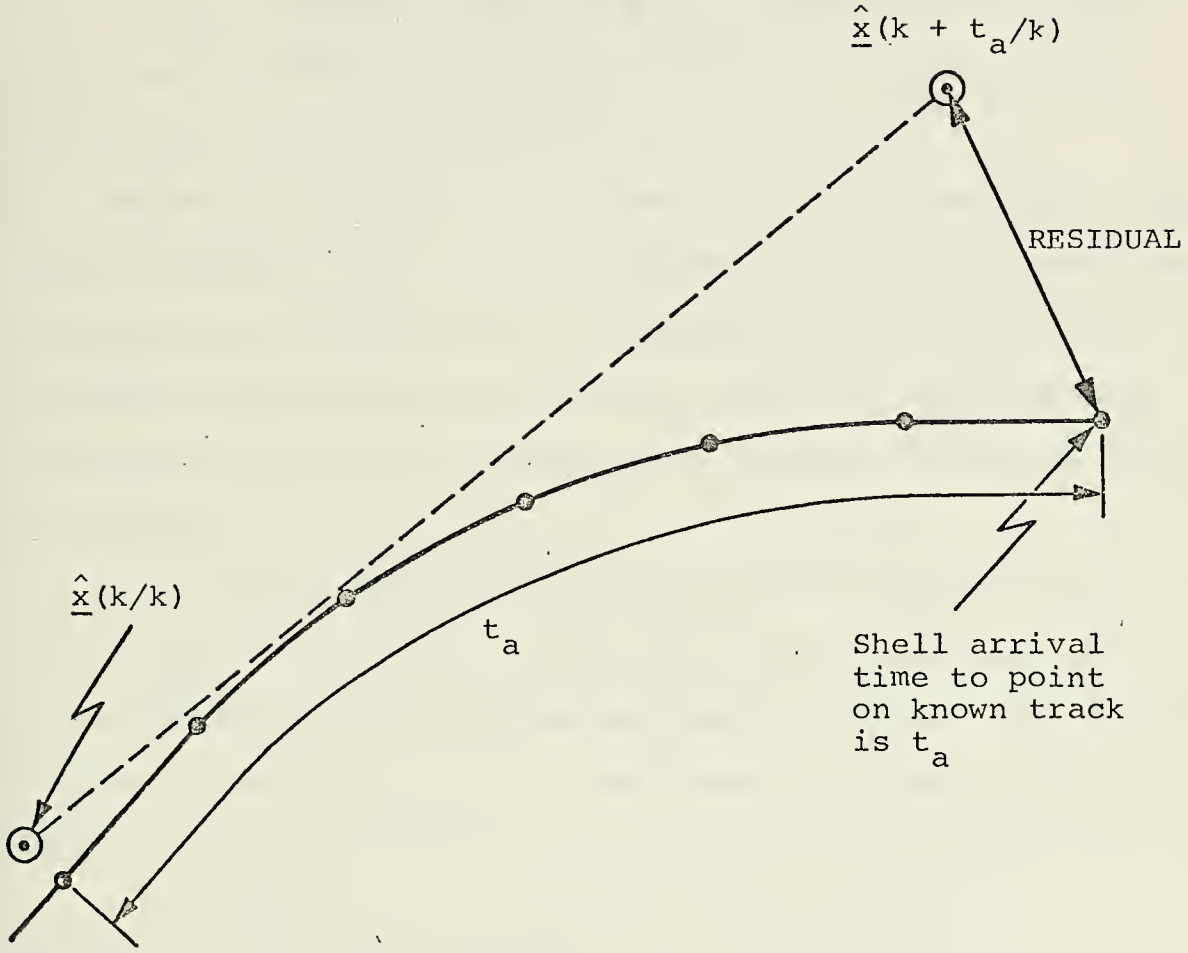
input parameters control the rotation, translation, and noise options applied.

C. SHELL-AT-TARGET ACCURACY

A feature which is an option in the MCSP provides approximate shell-at-target miss distances for additional filter evaluation. This feature is based on the firing table for a 5-inch 54-caliber gun and provides the approximate miss distances, or residuals, in X, Y, and Z directions and, also, the absolute miss distance with time of shell flight. Sections of the MCSP that are specifically responsible for these calculations are Subroutines ACCUR and STUDY.

The principles involved in obtaining the residuals will now be described. The first step required for implementation of the routine requires that the input XYZ track data be provided to program GUNFIRE, included as Appendix D, for offline calculation of the shell flight times to each point using interpolation in the 5-inch 54 firing table, included also in Appendix D. Program GUNFIRE is set up to provide these times for data points out to a range of 7500 yards and having an elevation of from 15 to 90 degrees above the horizon.

The known information includes the XYZ data points, the data point spacing, the shell times to each data point, and the $\underline{\phi}$, or state transition matrix, and the objective, as depicted in Figure 18, is to step back in time from a track point for which the shell arrival time, t_a, is known to a filter estimated point calculated an amount t_a earlier.



● - True track points

⊙ - Filter outputs

Figure 18. Shell-at-target Accuracy Diagram.

Knowing this estimated point $\underline{\hat{x}}(k/k)$ and the $\underline{\phi}$ matrix the filter's prediction of target location an amount t_a later is included in the vector defined by $\underline{\phi}^{(\frac{t_a}{T})}\,\underline{\hat{x}}(k/k)$ where T is the time between samples. The residual is then defined to be equal to the difference between the position states in the vector $\underline{\hat{x}}(k+t_a/k)$ and the actual track point.

Two major problems arise, however, in this approach. The first is that if t_a is not an integer multiple of track time increments, a filter estimate of states is not available. Secondly, implementation of this method generally requires raising the $\underline{\phi}$ matrix to a fractional power--a situation to be avoided.

A reasonable approximation to the desired results above is to step back in time to the first filter estimate prior to the desired time of filter estimation vector. This amounts to some fraction, α, of the time between samples, and the required vector of estimates is given, approximately, by $\underline{\hat{x}}(k+\alpha/k) = \underline{\phi}^{(\frac{\alpha}{T})}\,\underline{\hat{x}}(k/k)$. Hence,

$$\underline{\hat{x}}(k+\alpha+t_a/k+\alpha) = \underline{\phi}^{(\frac{t_a}{T})}\,\underline{\hat{x}}(k+\alpha/k+\alpha) \tag{52}$$

$$\simeq \underline{\phi}^{(\frac{t_a}{T})}\,\underline{\phi}^{(\frac{\alpha}{T})}\,\hat{x}(k/k) \tag{53}$$

$$\simeq \phi^{(\frac{t_a+\alpha}{T})}\,\hat{x}(k/k) \tag{54}$$

but $\frac{t_a+\alpha}{T}$ is an integer, thus solving the problem of raising $\underline{\phi}$ to a fractional power.

EXAMPLE: Given that the time for a shell to reach data point 100 is 9.7 time periods (the same as assuming a 1-Hz sampling rate) finds the filter's predicted position.

SOLUTION: Because $\underline{\hat{x}}(90.3/90.3)$ is not available, approximate it is $\underline{\phi}^{0.3}\underline{\hat{x}}(90/90)$. Then the filter's prediction vector at time 100 is given by

$$\underline{\hat{x}}(100/90) = \underline{\phi}^{0.3}\ \underline{\phi}^{9.7}\ \underline{\hat{x}}(90/90)$$
$$= \underline{\phi}^{10}\ \underline{\hat{x}}(90/90)\ . \qquad (55)$$

It should be noted that when the shell flight times are generated by GUNFIRE these are applicable only to the original track or a track rotated by the MCSP. If translation of a track is to be performed by the MCSP the shell-at-target miss distances generated will be erroneous, and this option should not be used.

D. ONLINE CALCULATION OF COVARIANCE MATRIX OF POSITION MEASUREMENT NOISE

The covariance matrix of measurement noise, $\underline{R}$, is a measure of the noise associated with the measurements and is used in calculating the gains. $\underline{R}$ is defined as $E[\underline{n}(k)\ \underline{n}^T(k)]$ where $\underline{n}(k)$ is the additive noise vector at time k.

In problems where the measurements are linearly related to the filter states, $\underline{R}$ can be approximated as a constant matrix for the entire track, an option available in the MCSP.

However, when the observations presented to the filter are range, bearing, and elevation (with noise assumed mutually independent) and the state equations are in rectangular coordinates, the required coordinate conversion generates a coupled, non-independent relationship among the noise terms

in the filtering coordinate system. This section presents a derivation to define the resultant $\underline{R}$ matrix for the given coordinate conversion.

The radar measures range, r, bearing, θ, and elevation, ϕ, and these measurements are made available to the estimator at sample times with the parameter k as an index. The measurements also include independent noise terms $n_1(k)$, $n_2(k)$, and $n_3(k)$ that are assumed to be characterized by random, white distributions with mean zero and known variances. This implies that

$$E[n_i(k)]_{i=1,2,3} = 0 \qquad \text{for all } k \tag{56}$$

$$E[n_1(k)n_1(j)] \qquad \begin{cases} 0 & j \neq k \\ \sigma_R^2 & j = k \end{cases} \tag{57}$$

$$E[n_2(k)n_2(j)] \qquad \begin{cases} 0 & j \neq k \\ \sigma_B^2 & j = k \end{cases} \tag{58}$$

$$E[n_3(k)n_3(j)] \qquad \begin{cases} 0 & j \neq k \\ \sigma_E^2 & j = k \end{cases} \tag{59}$$

$$\left.\begin{array}{ll} E[n_1(k)n_2(j)] & 0 \\ E[n_1(k)n_3(j)] & 0 \\ E[n_2(k)n_3(j)] & 0 \end{array}\right\} \quad \text{for all } k,j \tag{60}$$

The terms σ_R^2, σ_B^2, and σ_E^2 must be known. The coordinate system is the same as shown in Figure 2.

The rectangular coordinates of the target are

$$X(k) = r(k) \cos \theta(k) \cos \phi(k) \tag{61}$$

$$Y(k) = r(k) \sin \theta(k) \cos \phi(k) \tag{62}$$

$$Z(k) = r(k) \sin \phi(k) \; . \tag{63}$$

However, the output of the radar is

$$S_1(k) = r(k) + n_1(k) \tag{64}$$

$$S_2(k) = \theta(k) + n_2(k) \tag{65}$$

$$S_3(k) = \phi(k) + n_3(k) \tag{66}$$

and what the estimator receives is given by the noisy XYZ values denoted by $Z_1(k)$, $Z_2(k)$, $Z_3(k)$ and defined as follows

$$Z_1(k) = S_1(k) \cos S_2(k) \cos S_3(k) \tag{67}$$

$$Z_2(k) = S_1(k) \sin S_2(k) \cos S_3(k) \tag{68}$$

$$Z_3(k) = S_1(k) \sin S_3(k) \ . \tag{69}$$

If equations (64) - (66) are substituted into equations (67)-(69), trigonometric identities used with subsequent expansion, and it is assumed that the bearing measurement noise, $n_2(k)$, and elevation measurement noise, $n_3(k)$, are small so that $\cos n_2(k) \simeq 1$, $\sin n_2(k) \simeq n_2(k)$, $\cos n_3(k) \simeq 1$, and $\sin n_3(k) \simeq n_3(k)$,[3] we have

$$Z_1(k) = X(k) + v_1(k) \tag{70}$$

$$Z_2(k) = Y(k) + v_2(k) \tag{71}$$

$$Z_3(k) = Z(k) + v_3(k) \tag{72}$$

where $v_1(k)$, $v_2(k)$, and $v_3(k)$ represent additive noise and are given by

---

[3] In most radar tracking systems the standard deviations in bearing and elevation are less than .005 radians, or .286 degrees. The 3σ point, which includes 99% of this is, therefore, approximately 0.86 degrees. For comparison,
sin 0.86° = .0153 vs. .015 radians
cos 0.86° = .9999 vs. 1.

$$
\begin{aligned}
v_1(k) = &- r(k)\, n_3(k) \cos\theta(k) \sin\phi(k) \\
&- r(k)\, n_2(k) \sin\theta(k) \cos\phi(k) \\
&+ r(k)\, n_2(k)\, n_3(k) \sin\theta(k) \sin\phi(k) \\
&+ n_1(k) \cos\theta(k) \cos\phi(k) \\
&- n_1(k)\, n_3(k) \cos\theta(k) \sin\phi(k) \\
&- n_1(k)\, n_2(k) \sin\theta(k) \cos\phi(k) \\
&+ n_1(k)\, n_2(k)\, n_3(k) \sin\theta(k) \sin\phi(k)
\end{aligned} \tag{73}
$$

$$
\begin{aligned}
v_2(k) = &- r(k)\, n_3(k) \sin\theta(k) \sin\phi(k) \\
&+ r(k)\, n_2(k) \cos\theta(k) \cos\phi(k) \\
&- r(k)\, n_2(k)\, n_3(k) \cos\theta(k) \sin\phi(k) \\
&+ n_1(k) \sin\theta(k) \cos\phi(k) \\
&- n_1(k)\, n_3(k) \sin\theta(k) \sin\phi(k) \\
&+ n_1(k)\, n_2(k) \cos\theta(k) \cos\phi(k) \\
&- n_1(k)\, n_2(k)\, n_3(k) \cos\theta(k) \sin\phi(k)
\end{aligned} \tag{74}
$$

$$
\begin{aligned}
v_3(k) = &\; r(k)\, n_3(k) \cos\phi(k) + n_1(k) \sin\phi(k) \\
&+ n_1(k)\, n_3(k) \cos\phi(k)
\end{aligned} \tag{75}
$$

Using the assumed mutual independence of the noise processes and the state variables which implies $E[n_i\, n_j] = E[n_i] \cdot E[n_j]$, $i \neq j$, gives

$E[v_1(k)] = E[v_2(k)] = E[v_3(k)] = 0$, for all k, because

$E[n_1(k)] = E[n_2(k)] = E[n_3(k)] = 0$.

Then, if it is assumed that $r^2(k) \gg \sigma_R^2$, the following terms of the $\underline{R}$ matrix can be defined. In every case

$$E[v_m(k)\ v_n(j)] = 0 \text{ for } j \neq k \text{ and } m,n = 1,2,3 \tag{76}$$

$$\begin{aligned} E[v_1(k)\ v_1(j)] = {} & r^2(k)\ \sigma_E^2 \cos^2\theta(k) \sin^2\phi(k) \\ & + r^2(k)\ \sigma_B^2 \sin^2\theta(k) \cos^2\phi(k) \\ & + r^2(k)\ \sigma_B^2\ \sigma_E^2 \sin^2\theta(k) \sin^2\phi(k) \\ & + \sigma_R^2 \cos^2\theta(k) \cos^2\phi(k) \end{aligned} \tag{77}$$

$$\begin{aligned} E[v_1(k)\ v_2(j)] = E[v_2(k)\ v_1(j)] = {} & \\ & r^2(k) \cos\theta(k) \sin\theta(k) \sin^2\phi(k) \\ & \cdot [\sigma_E^2 - \sigma_B^2\ \sigma_E^2] \\ & + \sin\theta(k) \cos\theta(k) \cos^2\phi(k) [-r^2(k)\sigma_B^2 + \sigma_R^2] \end{aligned} \tag{78}$$

$$\begin{aligned} E[v_1(k)\ v_3(j)] = E[v_3(k)\ v_1(j)] = {} & \\ & \cos\phi(k) \sin\phi(k) \cos\theta(k) [\sigma_R^2 - r^2(k)\sigma_E^2] \end{aligned} \tag{79}$$

$$\begin{aligned} E[v_2(k)\ v_2(j) = {} & r^2(k)\ \sigma_E^2 \sin^2\theta(k) \sin^2\phi(k) \\ & + r^2(k)\ \sigma_B^2 \cos^2\theta(k) \cos^2\phi(k) \\ & + r^2(k)\ \sigma_B^2\ \sigma_E^2 \cos^2\theta(k) \sin^2\phi(k) \\ & + \sigma_R^2 \sin^2\theta(k) \cos^2\phi(k) \end{aligned} \tag{80}$$

$$\begin{aligned} E[v_2(k)\ v_3(j)] = E[v_3(k)\ v_2(j)] = {} & \\ & \sin\theta(k) \sin\phi(k) \cos\phi(k) [\sigma_R^2 - r^2(k)\sigma_E^2] \end{aligned} \tag{81}$$

$$E[v_3(k)\ v_3(j)] = r^2(k)\ \sigma_E^2 \cos^2 \phi(k) + \sigma_R^2 \sin^2 \phi(k) \quad (82)$$

A matrix summary of $\underline{R}$ for the three-dimensional coordinate system is

$$R = \begin{bmatrix} E[v_1(k)\ v_1(j)] & E[v_1(k)\ v_2(j)] & E[v_1(k)\ v_3(k)] \\ E[v_2(k)\ v_1(j)] & E[v_2(k)\ v_2(j)] & E[v_2(k)\ v_3(j)] \\ E[V_3(k)\ v_1(j)] & E[V_3(k)\ v_3(j)] & E[v_3(k)\ v_3(j)] \end{bmatrix} \quad (83)$$

This covariance matrix is included in the MCSP by the subroutine RNOISE and functions in the following manner. The current filter estimate is used to predict ahead one time increment to define the expected position states. These predicted XYZ values are taken by routine RNOISE, converted to RBE, and, along with the standard deviations, σ_R, σ_B, and σ_E input as data, which, when squared, give the necessary variances,are used to define the covariance matrix of measurement noise required for calculating the gains for the next filter estimate. That is, $\hat{\underline{x}}(k + 1/k)$ is used to obtain $\underline{R}$ for computing the gains needed to determine $\hat{\underline{x}}(k + 1/k + 1)$.

Again, this approach is an option which can be used with the Monte-Carlo simulation.

E. COVARIANCE MATRIX OF STATE EXCITATION

A filter designed to exactly follow a constant-velocity target will lag an accelerating target unless some technique

is incorporated to allow the filter to respond to the changes with increased gains to more heavily weight the latest observations. Increasing these gains is equivalent to increasing the bandwidth of the filter thus insuring that it is able to respond to deviations from the expected target performance.

The compromise made, however, is that additional measurement noise is able to enter into filter estimation and prediction through the increased bandwidth thus degrading the ability of the filter to reject measurement noise. There is, therefore, a balance which must be met between too small a covariance matrix of state excitation, $\underline{Q}$, and a resultant lagging filter and too large a $\underline{Q}$ with subsequent erratic filter behavior.

The MCSP can accommodate the use of a $\underline{Q}$ matrix in two ways--by using a constant input matrix of the anticipated covariance of state excitation in the calculation of all gains or by generating, online, $\underline{Q}$ matrices through a procedure that is adaptive to the residuals detected between predicted and estimated filter states. The alternative to these methods, as the MCSP currently exists, is to use no $\underline{Q}$ and input zeroes in its place.

The first of these methods requires some prior analysis of the target motion before the Monte-Carlo simulation is exercised, and with a modeled track, such as that designed for simulation with the MCSP, the variances can be evaluated using the track data.

The most direct method for obtaining terms to define a constant $\underline{Q}$ matrix is to take successive differences of the position data to approximate velocities, accelerations, and acceleration rates. Having these arrays of accelerations and acceleration rates in each dimension of the coordinate system, the mean and variance of each array can be calculated with the usual statistical procedures. The resultant quantities provide the necessary variances for determining $\underline{Q}$ for either constant-velocity or constant-acceleration models if the means produced are, in fact, close to zero (the assumed mean of random forcing). The implementation of this approach is included at the end of the track generating program in Appendix B, and the output of that program is also there showing the variances generated by the above technique.

While these variances are defined from actual track data it must be remembered that the resulting constant $\underline{Q}$ matrix will inevitably be sub-optimal since the accelerations or acceleration rates do not, in most cases, occur uniformly over the track; for some points $\underline{Q}$ will be "too small," thus not compensating for target motion and for other points $\underline{Q}$ will be "too large" allowing for measurement noise degradation of filter performance.

The use of a well-chosen constant $\underline{Q}$ matrix does, however, offer two distinct advantages. The first is that, if well chosen, it cannot help but improve the performance of a filter not dynamically adequate to follow a maneuvering target and, second, it offers simplicity and subsequent reduced

computation time and core area requirements in comparison to an adaptive technique.

The $\underline{Q}$ matrix, when implemented as a constant matrix, is defined by

$$\underline{Q} = \underline{\Gamma}\ E[\underline{w}\ \underline{w}^T]\ \underline{\Gamma}^T \tag{84}$$

where $E[w\ w^T]$ is the covariance matrix of state excitation, and $\underline{\Gamma}$ is necessary to relate changes in velocity or acceleration for the constant-velocity or constant-acceleration filters, respectively, through successive integrations, to the appropriate states. For the XYZ coordinate system, when the random forcing is assumed to be de-coupled,

$$E[\underline{w}\ \underline{w}^T] = \begin{bmatrix} \sigma_X^2 & 0 & 0 \\ 0 & \sigma_Y^2 & 0 \\ 0 & 0 & \sigma_Z^2 \end{bmatrix}$$

The matrix $\underline{\Gamma}$ for a de-coupled constant-velocity filter in three dimensions is given by

$$\underline{\Gamma}_V = \begin{bmatrix} \frac{T^2}{2} & 0 & 0 \\ T & 0 & 0 \\ 0 & \frac{T^2}{2} & 0 \\ 0 & T & 0 \\ 0 & 0 & \frac{T^2}{2} \\ 0 & 0 & T \end{bmatrix}$$

where T is the time between measurements. The constant-acceleration $\underline{\Gamma}$ matrix for a de-coupled target motion model is

$$\underline{\Gamma}_A = \begin{bmatrix} T^3/6 & 0 & 0 \\ T^2/2 & 0 & 0 \\ T & 0 & 0 \\ 0 & T^3/6 & 0 \\ 0 & T^2/2 & 0 \\ 0 & T & 0 \\ 0 & 0 & T^3/6 \\ 0 & 0 & T^2/2 \\ 0 & 0 & T \end{bmatrix} .$$

In the MCSP the matrices $\underline{\Gamma}$ and $E[\underline{w}\ \underline{w}^T]$ are input separately, and the necessary matrix products are formed to define the $\underline{Q}$ matrix.

The second of the two methods available is an adaptive technique described in (4). The Q matrix, at any point along the track, is defined to be

$$\underline{Q}(k) = K_1[\hat{\underline{x}}(k/k) - \hat{\underline{x}}(k/k-1)][\hat{\underline{x}}(k/k) - \hat{\underline{x}}(k/k-1)]^T - K_2 \cdot \underline{Q}(k-1) \qquad (88)$$

where $\hat{\underline{x}}(k/k)$ is the filter's state estimation vector at time k and $\hat{\underline{x}}(k/k-1)$ is the state prediction vector determined at time k-1. It is this residual between the predicted states at time k using knowledge through time k-1 and the estimated

states at time k which offers a measure of the state excitation acting to cause the discrepancy. The terms K_1 and K_2 are weighting constants used to limit the degree to which $\underline{Q}$ can change from one point to the next. By increasing K_1, $\underline{Q}$ becomes much more responsive to residuals and, also, noisy estimates while an increase in K_2 results in a type of damping on the $\underline{Q}$ matrix.

This is, to say the least, a seat-of-the-pants approach, but, given a very complex modeling scenario, it offers many points in its favor. First, it is very simple and easy to implement with small additional computation time and storage required. Secondly, it does, in fact, vary the magnitude of $\underline{Q}$ quickly, from point to point, rather than waiting for some threshold to be passed before alteration. Also, in a steady-state situation where the residual goes to zero, so does $\underline{Q}$, thus maintaining minimum bandwidth as desired.

It should be noted that the nature of gain calculations requires that the $\underline{Q}$ matrix generated at point k is used to determine the gains for calculating the filter estimates at time k + 1, but given a reasonably high sampling rate the loss in performance should not be significant.

This adaptive method is easily requested, as will be shown in the section on using the MCSP, and the logic for its implementation appears at the end of subroutine UPDATE.

F. INITIALIZATION

The initialization of a Kalman filter can greatly affect the speed with which filter estimates and predictions improve.

Many techniques are available, and three options exist in the MCSP for user selection.

The first is a default option which is used if the other two methods are not requested. The filter initializing vector, $\underline{\hat{x}}(0/-1)$, has its position states defined as the first observation, $\underline{z}$, and the remaining states are initialized to zero. In conjunction with this choice it is advisable to initialize the prediction covariance matrix with very large values to assure large gains during the transient period.

The second possibility is to read in the initial conditions, an option that will be described in the next section. This is fine if reasonable initial conditions are known, but care must be taken not to detract from filter performance by choosing erroneous values offering worse initial conditions than the default case. Again, it pays to choose a large prediction covariance matrix if the gains are not precalculated.

The third option is to have the MCSP generate "synthetic" estimates by solving difference equations, online. With this method it takes two measurements to generate a velocity estimate and a third to generate an acceleration estimate if needed. After either two or three measurements, depending on whether a constant-velocity or constant-acceleration model is used, an initializing estimation covariance matrix is generated as follows in the MCSP:

Constant-Velocity Model

$$\underline{P}(1/1) = \begin{bmatrix} 1 & 1/T & 0 & 0 & 0 & 0 \\ 1/T & 2/T^2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1/T & 0 & 0 \\ 0 & 0 & 1/T & 2/T^2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1/T \\ 0 & 0 & 0 & 0 & 1/T & 2/T^2 \end{bmatrix} \tag{89}$$

Constant-Acceleration Model

$$\underline{P}(2/2) = \begin{bmatrix} 1 & 1/T & 1/T^2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1/T & 2/T^2 & 3/T^3 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1/T^2 & 3/T^3 & 6/T^4 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1/T & 1/T^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/T & 2/T^2 & 3/T^3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/T^2 & 3/T^3 & 6/T^4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1/T & 1/T^2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1/T & 2/T^2 & 3/T^3 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1/T^2 & 3/T^3 & 6/T^4 \end{bmatrix} \tag{90}$$

The appropriate estimation covariance matrix is then used to generate a prediction covariance matrix for calculating the next gain matrix. With this option it is not necessary to input an initial prediction covariance matrix. The logic for its implementation can be found in subroutine UPDATE of the MCSP included as Appendix C.

IV. DESCRIPTION OF MONTE-CARLO SIMULATION PROGRAM (MCSP)

A. APPLICATION

The Monte-Carlo Simulation Program is designed for use in comparing 6th and 9th-order filter evaluations of airborne tracking methods and incorporates user controlled selection of the options mentioned in the previous sections and several other features that are discussed in this section. A listing of the program in FORTRAN IV appears in Appendix C. Comments appear liberally throughout the listing to aid in following the flow of the program as well as for pertinent information related to variable definitions and input instructions. The following sub-sections elaborate on the procedures to follow in using the MCSP and describe the output provided.

B. INPUTS

The input cards are described in sequence as required by the MCSP with description of the different arrangements dictated by the options requested. Unless otherwise specified the data should be double precision, D, format and right justified in the fields designated because calculations in the MCSP are done in double precision to minimize truncation errors.

CARD 1

COL(S)	VARIABLE (ARRAY) NAME	FORMAT	DESCRIPTION
1 - 10	LOOP	I 10	Integer specifying the number of Monte-Carlo runs desired
11 - 20	KVEL	I 10	An integer "1" specifies that true velocity data for the track is available and is to be input

COL(S)	VARIABLE (ARRAY) NAME	FORMAT	DESCRIPTION
31 - 44	LOOK	14 I 1	A 14-element integer array for outputing plots on the high speed printer. A "1" in the specified column produces a plot as follows: 31 - Mean miss distance when shell arrives (from shell-at-target calculations). Default option automatically prohibits this output if the gunfire option is not requested. 32 - Mean filter estimation error in X position calculation 33 - Same for Y coordinate 34 - Same for Z coordinate 35 - Variance of X position estimates 36 - Same for Y 37 - Same for Z 38 - Mean filter estimation error in X velocity calculation 39 - Same for Y 40 - Same for Z 41 - Variance of X velocity estimates 42 - Same for Y 43 - Same for Z 44 - Estimated target tangential velocity in ft/sec
51 - 70	TIME	D 20.0	Time between measurements in secs.

CARD 2

COL(S)	VARIABLE (ARRAY) NAME	FORMAT	DESCRIPTION
1 - 5	N	I 5	Integer specifying the number of states, i.e. order of filter such as 6 or 9
6 - 10	NN	I 5	An integer specifying the number of track points or measurements

COL(S)	VARIABLE (ARRAY) NAME	FORMAT	DESCRIPTION
11 - 15	OPT	I 5	An integer "1" causes the program to generate synthetic measurements for filter initialization
16 - 20	BEGIN	I 5	An integer "1" signifies that the filter initialization vector $\hat{\underline{x}}(0/-1)$ is to be input data
21 - 25	IR	I 5	An integer "0" causes the program to generate, online, $\underline{R}$ matrices as discussed in III.D. An integer "1" signifies that a constant $\underline{R}$ matrix is input data.
26 - 30	ADAPTQ	I 5	An integer "1" incorporates the adaptive $\underline{Q}$ matrix calculations
31 - 35	IG	I 5	An integer "1" causes the MCSP to punch out the gain matrices for each point on the track with one row of a matrix per card and having two coded integers in the first 10 columns of each card. The first specifies the track point and the second gives the row of the gain matrix for that point on the track. The gains are punched in a D format in columns 11-30, 31-50, and 51-70 of each card. NOTE: It is necessary to change the second control card of the source deck from // EXEC FORTCLG to // EXEC FORTCLGP when using this option.
36 - 40	IGAIN	I 5	This integer parameter controls the handling of gains in the MCSP. An integer "0" causes gains to be generated online for each MC run. An integer "1" generates gains on the first run with a noiseless track and uses these gains for all subsequent noisy tracks. An integer "2" causes gains to be read in by rows, 3 number per card. The data should be in D format in 20 column fields beginning in column 11.
41 - 80	LABEL	10 A 4	A 10-element alphanumeric array for run identification that appears at beginning of output

CARD 3

COL(S)	VARIABLE (ARRAY) NAME	FORMAT	DESCRIPTION
1 - 15	RR	D 15.0	Standard deviation of noise added to range data in yards. In MCSP this is added to .001· Range to provide a realistic figure
16-30	RB	D 15.0	Standard deviation of noise added to bearing data in radians
31-45	RE	D 15.0	Standard deviation of noise added to elevation data in radians
46 - 60	K1	D 15.0	Weighting constant for adaptive Q option which multiplies previous Q
61 - 75	K2	D 15.0	Weighting constant for adaptive Q option which multiplies new residual matrix

CARD 4

COL(S)	VARIABLE (ARRAY) NAME	FORMAT	DESCRIPTION
1 - 5	IDIR	I 5	An integer which specifies the rotation of the target track desired: 0 - no rotation 1 - 45° counterclockwise 2 - 90° counterclockwise 3 - 200.5° counterclockwise
6 - 10	INDEX	I 5	An integer controlling the addition of measurement noise to the track 0 - no noise 1 - add noise
11 - 15	IGUN	I 5	An integer "1" causes MCSP to calculate and output shell-at-target residuals
16 - 35	TRANSX	D 20.0	Desired translation of all X-axis data points in yards
36 - 55	TRANSY	D 20.0	Same for Y axis
56 - 75	TRANSZ	D 20.0	Same for Z axis

Card 5 begins the input section for matrices, and, therefore, the description given is for a typical card of the matrix with an indication of the number of cards that should be in the matrix. This section also depends upon the options that have been chosen above, and the possible combinations are discussed below.

1 - If gains are to be read in (IGAIN = 2) they are done so here under the format specified under the IGAIN = 2 description. There should be NN · N cards. (Next go to #1 below to read $\underline{\phi}$ matrix.)

The following optional matrices apply when gains are calculated by the MCSP.

2 - If the $\underline{R}$ matrix is to be computed by the MCSP and synthetic measurements for initialization are not requested (OPT $\neq$ 1) the following sequence applies.

(a) Read initial prediction covariance matrix, $\underline{P}(0/-1)$, an N X N matrix. Data is read with an 8D10.5 format, thus there are N cards for 6th-order and 2·N cards for 9th-order with the 9th element of each matrix row on a card by itself in the first 10 columns following the card with the first 8 elements punched.

(b) Read initial matrix of random forcing covariances, $E[\underline{w}\ \underline{w}^T]$, a (3 X 3) matrix with the same input format as (a).

(c) Read the (3 X N) $\underline{\Gamma}$ matrix with the same format as (a).

3 - If $\underline{R}$ is to be a constant matrix, the instructions in 2 above apply with the addition of reading the (3 X 3) $\underline{R}$ matrix between (a) and (b). The format is the same as 2 (a) above.

4 - If gains are calculated online and synthetic measurements are desired for filter initialization (OPT = 1) it is not necessary to provide a prediction covariance matrix. Therefore, in this case either the matrix of expected forcing covariances or a covariance matrix of measurement noise should appear first in this section of optional matrices.

These optional matrices having been arranged correctly, the next two matrices follow for all four possibilities.

1 - The N X N plant dynamics matrix, $\underline{\phi}$, is read. Again, the format follows that described in case 2 (a) above.

2 - The 3 X N (for a three-dimensional problem) measurement matrix, $\underline{H}$, is read next with the same format as for $\underline{\phi}$. There should be either six or 12 cards depending on the order of the filter.

The next major group of cards pertains to the track data. The format for all track data is to read the XYZ components for a given point with a 3D20.0 specification for fields beginning in column nine. If true velocities are available and to be read they should be punched according to the same format, and the velocity data card for a given track point should follow immediately after the corresponding position data card and prior to the next point's position data card. There should be either NN or 2 · NN cards in this segment depending on whether velocity data is available or not.

Following the track data, if IGUN = 1 implying that the shell-at-target calculations are desired, should appear the shell flight times punched one per card in the first 20 columns. There should be NN of these cards, and the format statement controlling their input is D20.0.

The last two cards possibly needed are for the initial conditions for the state vector $\underline{\hat{x}}(0/-1)$, called for when BEGIN = 1. The same format is followed as for the track data with the position data on the first card and velocity data on the second. In the case of a 9th-order filter the acceleration initial conditions are automatically set to zero.

This concludes the discussion of input data organization, and a complete sample data set is included in an example in Appendix E.

C. OUTPUT

Most of the output provided by the MCSP is self-explanatory, but a summary is included here with some additional insight into what the output actually means and a few peculiarities that the user should be aware of. A complete sample output is included with the example in Appendix E.

The first general output segment includes specification of some of the input parameters as well as the initial condition matrices. The matrices printed depend on what is relevant to the run requested. For example, if gains are read in, no prediction covariance matrix or random forcing matrix is provided. Also, if the adaptive $\underline{Q}$ method is used the actual initial state excitation matrix is printed instead of the output for constant-$\underline{Q}$ filter runs which includes the variances of random forcing that are provided as input data.

The next output segment, if requested, is the performance table showing the shell-at-target residuals. Because it takes several seconds for a shell to reach the target after filtering has been initiated, the output shows no residuals until this flight time has been satisfied. In the case of the track designed for the MCSP with no track translation, this amounts to 36 time increments. Also printed is a figure of merit for the given filtering scheme which is the average shell-at-target miss distance for those track points where it is applicable.

Following the gunfire figure of merit is a filter performance factor representing the rms error in filter position estimates averaged over the entire track. If true velocity data is available, a similar performance factor is printed which represents the rms error in filter velocity estimates averaged over the entire track.

The succeeding output table displays actual filter estimation accuracy by showing the mean and variance of the error between the filter estimate and the true track data. If velocity data is not available, the output for the velocity statistics presents the mean and variance of the estimates themselves.

The last and optional set of output is the plots requested on the first data card. These are produced by the routine PLOTP with one plot per page and headings already provided for the three-dimensional XYZ coordinate system.

V. SUMMARY OF REPRESENTATIVE SIMULATION RUNS

A. DESCRIPTION OF RUNS AND NUMERICAL RESULTS

This section presents the results of the simulations using some of the various combinations of options available in the MCSP. Rather than include the extensive outputs of the simulations only relative figures of merit for the shell-at-target accuracy calculations and filter performance factors are listed in Table II to provide some insight into the effects of possible combinations of selected options. In addition, results are included that were obtained using the MK-86 filter simulation developed in [5].

Descriptions of the various runs follow that include mention of the unique options used for each run. Unless otherwise specified the controls and initial conditions used in all runs include:

(a) 100 Monte-Carlo runs,

(b) $\underline{\phi}$, $\underline{\Gamma}$ and $\underline{H}$ are the same as described previously for 6th and 9th-order filters,

(c) $\underline{P}(k/k-1)$ is "large" (1.D05 for all diagonal terms),

(d) Covariances of random forcing input matrix = 0,

(e) Standard deviations of Gaussian noise added to track are $\sigma_R = 5 + .001$ X Range, $\sigma_B = .002$ radians, $\sigma_E = .002$ radians,

(f) No rotation or translation of track data,

(g) Initialization of filter by letting the first observation define the position states in $\underline{\hat{x}}(0/-1)$.

Reference made to "Constant Q" in the descriptions signifies that the covariances of random forcing used for defining the constant $\underline{Q}$ matrix are those calculated by successive differences in the track generating program. It should be kept in mind that this process is based on the analysis of a noiseless track, and the use of the covariances thus obtained are inherently small for the noisy-track simulations with subsequent estimator error.

Run Number	Order of Filter	Special Features
1	6	1 Monte-Carlo run No additive noise on track
2	6	IGAIN = 0 (gains calculated every run)
3	6	IGAIN = 1 (gains calculated on first run with noiseless track)
4	6	IGAIN = 1 Constant $\underline{Q}$ (values listed in Appendix B)
5	6	Same as 4 OPT = 1 (synthetic initialization) $\underline{P}(k/k-1) = 0$
6	6	Same as 4 BEGIN = 1 ($\hat{\underline{x}}(0/-1)$ is set to 0)
7	6	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .1$, $K_2 = .9$
8	6	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .5$, $K_2 = .5$
9	6	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .9$, $K_2 = .1$
10	6	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .1$, $K_2 = .9$ IDIR = 1 (45° rotation of track)

Run Number	Order of Filter	Special Features
11	6	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .5$, $K_2 = .5$ IDIR = 1
12	6	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .9$, $K_2 = .1$ IDIR = 1
13	9	1 Monte-Carlo run No additive noise on track
14	9	IGAIN = 1
15	9	IGAIN = 1 Constant $\underline{Q}$
16	9	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .1$, $K_2 = .9$
17	9	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .5$, $K_2 = .5$
18	9	IGAIN = 0 Adaptive $\underline{Q}$ with $K_1 = .9$, $K_2 = .1$
19	9	Same as 18 Only position and velocity estimates used for shell-at-target accuracy calculations
20	6-9	Model of MK-86 estimator No additive noise on track 1 Monte-Carlo run

The second column of Table II lists shell-at-target figures of merit normalized to the results obtained with the MK-86 estimator. This is done to indicate relative performance against what must be considered a severe test of the filters studied. Due to compatability problems between the MK-86 estimator and the MCSP the results for run 20 are based on a noiseless track with one Monte-Carlo simulation. This produces optimal statistics since noise on the track degrades filter performance, and the comparison between the MK-86

estimator and the other filters in the study is slanted in favor of the former.

Additional insight into the potential success of the fire control system estimators in generating accurate firing orders is reflected in Table III where summaries of the numbers of hits within several radial miss distances of the target are tabulated for the better filters. Again, these figures would undoubtedly improve given a less maneuvering target, but it is worthwhile to know the possible consequences of a threat as reflected in the modeled track. The numbers shown are out of a total of 197 shells fired in the simulation.

B. EVALUATION OF RESULTS

An analysis of the numerical results presented in Table II reveals several items of interest. In this section the influence of such factors as the method of determining and using gains, initialization, type of $\underline{Q}$ matrix used, and direction of approach are empirically compared, and possible explanations for the trends shown are discussed.

The motivation for runs 1-3 and 13-14 was to check the reliability of the Monte-Carlo statistics and to compare the various techniques for determining and using gains. With noise of mean zero added to the track in runs 2, 3, and 14 the filter estimate errors should have been consistent with those generated in runs 1 and 13 (single run, no additive noise simulations). In addition, runs 2 and 3 were executed

TABLE II

ESTIMATOR PERFORMANCE TABLE

Run Number	Normalized RMS Shell-at-Target Miss Distance	RMS Mean Filter Position Estimation Error - yds	RMS Mean Filter Velocity Estimation Error - yds/sec
1	5.49	463.83	79.02
2	5.48	463.67	78.99
3	5.48	463.80	78.99

20	MK-86 Estimator	0	3	6	12

to test the reliability of using gains calculated on the first run having a noiseless track against the results of a simulation having gains calculated on every run. As can be seen in Table II both tests showed desired results--the statistics for 100 runs with noisy tracks gave the expected mean errors, and the gain calculations on the first run having a noiseless track provided reliable results if used for all other runs having noisy tracks. It should be noted that calculating and using gains in this manner is only possible when $\underline{Q}$ is a constant matrix. Attempts to use IGAIN = 1 with adaptive $\underline{Q}$ simulations resulted in major discrepancies because the noise on the track is a major factor influencing the magnitude of the $\underline{Q}$ matrix from point to point, and the noiseless track did not provide similar residuals.

Runs 4-6 were designed to evaluate the various initialization methods, and the results show only minor variation.

A most interesting trend in the application of the adaptive $\underline{Q}$ option is revealed by runs 7-12 and 16-18. It is apparent that for the track used it is beneficial to provide some damping in the form of a high K_1/K_2 ratio. A plausible explanation is that additive noise can cause undesirable residual variation and subsequent erratic $\underline{Q}$ matrices if allowed to too heavily weight the updated $\underline{Q}$ matrix. Selecting the correct ratio shows obvious improvement in filter performance and provides better performance factors in Table II than those for the constant Q runs with 6th and

9th order filters. However, the numbers of hits within the several radii shown in Table III do not show the same pattern, and this suggests that if the requirement to have a few shells within a small radius is more important than having a lot of shells within a larger radius, then a less responsive $\underline{Q}$ matrix calculating technique is needed. Because in most airborne filtering situations the random forcing on the target is unknown, the successful implementation of an adaptive technique seems to be the only way to deal with all possible situations.

The rotation of the track in runs 10-12 was provided to check that option and confirm that the trends shown are not functions of the direction of approach of the target.

A final area of comparison is between the 6th and 9th order filters with similar options used. As expected the 9th order filter provided smaller mean filter estimation errors because of its ability to exactly follow a constantly-accelerating target. Specific runs for comparison are 4 and 15 for the constant $\underline{Q}$ runs and 9 and 18 for the best of the adaptive $\underline{Q}$ runs. As shown in Table II the two methods for determining $\underline{Q}$ provide similar results for the 6th-order filter with the constant $\underline{Q}$ method producing slightly smaller filter estimation errors. In the case of the 9th-order filter the adaptive $\underline{Q}$ technique provides superior position estimates, but the constant $\underline{Q}$ method is superior in generating velocity estimates.

A most noteworthy incompatibility is the contradiction shown for shell-at-target miss distances between 6th and 9th-order estimators. From Table II it is suggested that the 6th-order filters offer superior performance in minimizing the miss distances, but the actual superiority belongs to the 9th-order filters as evidenced by Table III. The discrepancy can be explained by the fact that the 6th-order filters consistently provide miss distances that are in the range from 50 to 150 yards but fail to reduce this substantially whereas the 9th-order filters do provide these minimum miss distances but are substantially worse at ranges greater than 3000 yards due to the effects of acceleration estimation errors. At great distances these acceleration estimation errors are important due to the larger flight times of the shells.

Run 19 was included as a special study to determine the shell-at-target accuracy for the filter in run 18 when only position and velocity estimates were used for prediction. Some internal changes were required in the MCSP to obtain these results that are intended to reinforce the comments made above.

The results for run 20 present the performance of the existing system against the scenario of the MCSP track. This is a combination 6th-9th order filter using only position and velocity estimates to generate predicted target location for determining gunfire orders.

VI. CONCLUSIONS AND RECOMMENDATIONS

Judging from the results presented in the previous section the techniques and derivations presented in this thesis have been shown to be applicable to airborne tracking problems with possible results superior to those obtained using present estimators. The use of a Monte-Carlo simulator has been beneficial in insuring that the results obtained are statistically legitimate for the scenario studied. Also, the capacity to vary the implementation of the many options available has made it possible to determine those factors that offer the greatest potential for improved estimator performance.

While the results presented in this thesis are encouraging, the scope of the study must be reiterated in order to avoid drawing too broad conclusions regarding the applicability to aircraft tracking problems. The track developed and used was selected because of its common use today in typical aircraft tactics, but much additional analysis would be necessary to categorically accept the relative capacities of the several filters presented herein. It is the adherence to such an analytical approach that can insure that the filters acquired for modern gunfire control systems are capable of handling the threats they are expected to experience.

The results have shown that given a complex target approach, basically simple filters are capable of surprising results if reinforced by techniques designed specifically for the model scenario. The online generation of the covariance matrix of measurement noise and adaptive covariance matrices of random forcing are examples that contribute to minimizing filter estimation errors. These features are, of course, dependent upon the availability of computation capacity, but with the advent of smaller, faster, and less expensive computers the restrictions imposed are becoming more liberal all the time.

This thesis was intended to correlate some of the important concepts pertinent to airborne tracking filters into an easily used simulation program for current and future study. Some areas that appear to offer additional potential for filter improvement and simulation accuracy include continued study in the field of adaptive covariance matrices of random forcing, a feature seen to be most powerful in this thesis, further work in the area of computation time and storage requirements for implementing various filtering approaches, and refinement of the shell-at-target accuracy calculations. Furthermore, implementation of simulation-generated techniques into actual models for testing is mandatory to provide feedback for refining the simulators, thus saving investment in inferior systems due to acceptance of incorrect simulation results.

APPENDIX A

PROGRAM LISTING FOR MONTE-CARLO RUN REQUIREMENT EVALUATION

The program written for analyzing the existing generators of normally distributed random numbers is included in this appendix. It provides statistics for empirical mean and standard deviation within 5, 10, 15, 20, and 25 percent of the desired standard deviation for ensembles taken a variable number of times.

In the program the following variables can be altered to obtain additional statistics describing expected results in Monte-Carlo simulations

ITER - The number of samples in each ensemble

N - The number of ensembles determined by data cards using an I5 format in the first five columns.

The program is written to terminate when N = 5000, but this can be revised by referring to the statement identified by NORM0094.

APPENDIX B

TRACK GENERATING PROGRAM

The following program generates the track data used in the simulations conducted for comparison in this thesis. Both position and velocity data are produced for each of the 233 points on the track, and, in addition, the means and variances of accelerations and acceleration rates are calculated and averaged over the entire track to provide data used in the "Constant Q" simulations.

The results of the latter calculations follow, and it should be remembered that the validity of using the variances in defining a constant Q matrix is dependent on having enough sample points to insure accelerations and acceleration rates with the assumed mean of random forcing (zero).

Mean acceleration in X direction:	-1.675	yd/sec^2
" Y " :	-1.419	"
" Z " :	0.772	"
Variance of acceleration in X direction:	45.739	$(yd/sec^2)^2$
" Y " :	296.869	"
" Z " :	224.467	"
Mean acceleration rate in X direction:	-0.131	yd/sec^3
" Y " :	-0.351	"
" Z " :	0.207	"
Variance of acceleration rate in X direction:	106.984	$(yd/sec^3)^2$
Variance of acceleration rate in Y direction:	957.846	"
Variance of acceleration rate in Z direction:	4249.27	"

APPENDIX C

LISTING OF MONTE-CARLO SIMULATION PROGRAM (MSCP)

A complete listing of the Monte-Carlo Simulation Program is included herein. For user convenience the statement numbers are in ascending order allowing for easy location of designated statements, and the cards are labeled in the right margin for reference and ordering if required.

Variable and array descriptions appear at the beginning of the program with instructions for the input parameters immediately following each READ statement. Format statements controlling headings on the output plots are included in the program statements MCSP0600-MSCP0694.

```

APPENDIX D

LISTING OF SHELL FLIGHT TIME INTERPOLATION PROGRAM

The program that interpolates in the 5 in - 54 gunfire table (included after the program listing) to generate the shell-at-target flight times is included in this appendix. In its present form it can provide times for tracks operating in a region bounded by

minimum range	- 500 yards
maximum range	-7500 yards
minimum elevation angle	- 15 degrees
minimum elevation angle	- 90 degrees.

If track data points fall outside of these limits the program can be easily expanded by enlarging the arrays and revising the linear interpolation equations.

APPENDIX E

SAMPLE SIMULATION

A sample problem is included to display a representative input data set and the output that can be expected from the MCSP. A description of the desired simulation follows:

Number of Monte-Carlo runs - 100,

Track has 233 points with 4-Hz, sampling rate with approximate velocity data available,

Direction of approach - 45°,

Order of filter - 6,

Initialization by synthetic measurements is desired,

Adaptive $\underline{Q}$ with $K_1 = .9$, $K_2 = .1$,

Noise statistics are $\sigma_R = 5.0 + .001$ X Range

$\sigma_B = \sigma_E = .002$ radians,

Shell flight times are available, and shell-at-target accuracy calculations are desired,

$\underline{\phi}$, $\underline{\Gamma}$, and $\underline{H}$ are standard 6th order matrices,

Desired output includes all available plots.

An abridged listing of the input data appears next followed by representative portions of the output produced.
